According to Dr. Balfour, in Sicily, the fibre is called "Zamharoune," and serves to make ropes and mats, and in South America the fibre of "pita" is much used for making ropes of large sizes.

The fibre and rope of *pita* are articles of commerce in the south of Spain. Mr. Roman de la Sagra recommends the introduction of some new species from Guatemala and Columbia, where they are known as "Cabulla" and "Coraza." These are species of "fourcroya" which produce excellent fibres. The "fourcroya gigantea" is common at St. Helena, and has been introduced into Madras. The island of Madeira sent fibres of "pita" to the Exhibition of 1861. Mexico also sent thread and paper made from the American aloe.

The name of "pita" seems to have been given also to similar fibres obtained from *Bromelia* and *Yucca*. Dr. Hamilton says that this fibre weighs less than hemp by one-sixth. He considers it more resisting and durable than hemp and prefers it for cables, fishing nets, &c., on account of its resistance to damp. In an experiment made on board her Majesty's Ship *Portland*, a log line 300 feet in length and made of fibre of "pita" shrank 16 feet only, whilst a hemp line of the same length shrank 21 feet. Besides, the contraction of the "pita" ceased on the third day, whilst that of the hemp ropes continued to shrink.

Labillardiere relates that at Amboyna the aborigines obtained from the hybrid aloe, commonly called *Agave divipara*, a long and handsome fibre equal to that of our best hemp. The aloe grows well in the north of Africa, and the French, since their occupation of Algeria, pay great attention to it. The result of some experiments made in Paris shows that the aloe rope from Algeria will bear a weight of 2,000 kilogrammes (about 4,480 lb.), whilst Manila hemp of the same thickness will not bear more than 400 kilogrammes. At Toulon fibres were steeped in sea water for six months, after which the aloe bore a weight of lbs. 3,810, whilst hemp only bore 2,538, leaving a difference of lbs. 1,272 in favor of the former. Lastly, according to experiments made by Mr. Hornsby and reported to the Society of Agriculture of India, aloe ropes have always been found superior, not only on account of their resistance, but also on account of durability, to ropes of other kinds, such as jute, Manila hemp, abaca, &c. The chapter ends with these almost prophetic words:—

"The fibre is sufficiently good to furnish an article of commerce of the first order, and is destined to acquire in the future a considerable value, especially since the prejudice against white cordage seems to be disappearing. It is to be hoped that important experiments will be undertaken to ascertain what are the best conditions in which the leaf should be cut, and also whether it is not possible to extract the fibre by mechanical means. Care should also be taken, when preparing the ropes, not to cut the fibres when turning them; this is a delicate operation which should be entrusted to professional rope-makers.

"The aloe grows where nothing else will grow, without cultivation, without expense. No injury whatever can be done to it either by drought, inundations, cyclones, or any of the innumerable evils which often prejudicially affect the cultivation of ordinary crops."

As already explained above, the aloe produces at present, in fibre, an average of about 3 per cent of its weight, whilst with the old apparatus 2 per cent was hardly realised. The fibre of aloe packed in bales was sold some time back in the London market at an average price of from £30 to £32 per ton, but recent accounts show sales at £38 and £40, or an advance in price of £8 to £10 per ton. These figures prove great stability in the price of the article, and are explained by the following extract from Dr. Forbes Royle's work already mentioned above:—

"It has often been said that the only means of knowing the value of fibre or of any other produce is the price which it realises in the market. This is very true as regards known articles, but, if a new produce be sent to a market, few persons will buy it, because it requires new machines. I have been told that many years must elapse before a new article can draw the attention of purchasers; this is likely, for it is one of the laws of commerce."

As regards planting, much need not be said. The aloe may be planted in all seasons, and from saplings of one year, or two, or even three years old. It is best however to plant from seed. The older the aloe is when transplanted, the sooner the stem is formed. Aloes planted from seed or from saplings of the first

year take five years to attain their full development, whilst, if transplanted at a height of from 18 to 20 inches, they are fully developed in three years.

In the Mauritius may be seen growing spontaneously the following species of aloe:—

- (1) "*Agave Americana*" (American or blue aloe).
- (2) "*Agave Angustifolia*" (aloes with small leaves).
- (3) "*Fourcroya Gigantea*" (green aloe).
- (4) "*Fourcroya Gigantea*, Var" (cabbage or Malgache aloe).

The species known in the Mauritius as green aloe came originally from South America and the Antilles.

RUST AND MILDEW.

READ the following letter from W. WILSON, M.A., Director of Revenue Settlement and Agriculture, Madras, to the Secretary to Government, Revenue Department, dated 5th May 1883, No. 540.

I have the honor to submit, for the consideration of Government,

* Letter No. 570, dated 6th April 1883.

† Letter No. 192-85, dated 20th April 1883, in original, to be returned.

remarks on rust and mildew received from the Agricultural Reporter * and Mr. Benson,† Special Assistant to the Collector of the Nilgiris, to whom and to Mr. Cox, Deputy Director of Revenue Settlement, G. O., No. 327, dated 5th

March 1883, was referred for report.

2. Messrs. Benson and Cox seem to have thought the scope of the inquiry confined to wheat, but I do not understand this to have been the intention of the Government of India. Wheat is grown but to a small extent in this Presidency, and the common cereals of the country would, it is believed, be found to be quite as subject to attack by rust when the conditions are favourable as wheat is.

Mr. Cox has sent no report as owing to wheat not being grown in the part of the country where he is now working, he had no opportunity of learning anything about "wheat mildew." The area of wheat in this Presidency according to the returns for the latest available year, 1881-82, was only acres 27,758 distributed among twelve districts as marginally noted. Mustard was grown on 2,847 acres in eight districts, but in only four of them—Bellary, Godavari, Salem and Kistna—were wheat and mustard grown in the same district: there is no information as to whether they were grown in the same fields, and no information so far as inquiry has gone as to whether, when rust attacks cereals, the attack is worse when mustard is grown in the same fields. The barberry is not found in the plains, but General Morgan, whose note on the subject is enclosed in Mr. Benson's report, scouts the idea that rust in Nilgiri wheat has any connexion with the barberry, several varieties of which are very common on the hills and in the immediate vicinity of fields the wheat on which is free from rust. This alone would not disprove the connexion, contended for by Mr. Carruthers, for the necessary conditions for the

germination of the spores may not have been present in the instances referred to. The conditions necessary to rust on the Nilgiris, as described by Mr. Benson and General Morgan, are similar to those under which it appears in England—continued damp and moisture: "the only check to rust," Mr. Carruthers says, "is a bright sun and a warm dry atmosphere."

3. The Agricultural Reporter on the other hand states his experience in India to be that rust and other fungoid diseases are invariably the result of a sudden drought following a fine growing season, and that the best cure is the "restoration of the conditions of luxuriant growth," in other words, a good downpour of rain or artificial irrigation freely applied. This is altogether opposed to the views of Mr. Carruthers, according to which rust is quite dormant in drought, and is possible only when the fungoid spores can obtain a sufficient supply of moisture to enable them to germinate.

4. As a preventive, General Morgan suggests the saturation of the seeds for four-and-twenty hours before sowing in a solution of the sulphate of iron: Mr. Robertson states that saturation in a solution of the sulphate of copper has prevented "smut" at the farm, but has had no effect in preventing "rust."

5. I have in conclusion to make the following general remarks:—On the supposition that the conditions favorable to rust are in India similar to those described by Mr. Carruthers for England, viz., a continuance of cold damp weather, it would appear that the crops in this Presidency can but seldom suffer seriously from it. "A few bright sunny days arrest the progress of the fungus, and vigorous plants overcome the attack without any real injury." We are now here very long without "bright sunny days," and the only crops that on *a priori* considerations might be expected to be attacked with rust are those which are sown after the first burst of the S. W. monsoon, and they would suffer seriously only if the monsoon were unusually protracted, and

unrelieved by frequent intervals of bright sunny days, an event which we have not often to deplore.

ENCLOSURES.

Letter from W. R. ROBERTSON, Esq., M.R.A.C., Agricultural Reporter to the Government of Madras, to the Director of Revenue Settlement and Agriculture, Madras, No. 570, dated Saidapet, 6th April 1883.

I have the honor to reply to paragraph 2 of the Government of India's Circular, No. 11-A of the 18th February last.

2. Wheat is grown on a very limited area of land in this Presidency. Our cropped area varies from 22 to 25 million acres, yet we seldom, in any single year, have more than 30,000 acres under wheat. The variety of wheat generally grown is spelt *Triticum spelta*, the husk of which adheres to the grain. Ordinary wheat, *Triticum sativa*, is grown on a very small scale. The wheat is produced chiefly in Kurnool, Cuddapah, Kistna, Coimbatore, and the Nilgiris.

3. Mustard is almost unknown as a field crop in South India. It is grown on a small scale in Ganjam, Godavari, Nellore, and the Nilgiri districts. Except in the last-mentioned districts, I am aware of no place in South India where mustard and wheat are likely to be grown on the same land. In England, light wheat-soils, in some localities, are occasionally cropped by a catch crop of mustard, which is either cut and used as fodder, or is eaten on the land by sheep.

4. According to my experience in South India "mildew," *Puccinia graminis*, is not nearly so prevalent as "rust," *Tricobasis oblongo-vera*; though it appears to be generally admitted that the two parasites take their origin from the same spores. The majority of our unirrigated crops, and it is those that are most liable to be attacked by parasitic disease, are very short-lived, usually maturing in about 4½ months from seed-time, and probably this is the reason why the disease seldom passes beyond the "rust" stage when attacking these crops.

5. My experience is that these parasitic diseases usually show themselves when a fine growing season is suddenly stopped and followed by a drought. A sudden check in luxuriant vegetable growth is almost invariably followed by an attack of the fungoid disease—"rust." I have found at such times that a good shower of rain has restored luxuriant growth, and enabled the plant to throw off the disease; and I have seen the same result produced when the soil has, at such times, been freely irrigated. I believe that when the plant is attacked, when young, the best means to take to combat the disease will be those which restore or secure luxuriant growth.

6. We have successfully, at Saidapet, kept in check the fungoid diseases known generally as "smut" by dressing all the seed-corn with a solution of sulphate of copper; but this dressing has had no effect in preventing "rust."

Letter from R. S. BENSON, Esq., Special Assistant Collector in charge, to the Director of Revenue, Settlement, and Agriculture, Madras, No. 102-85, dated Ootacamund, 20th April 1883.

I have the honor to report the result of inquiries made by me regarding rust and mildew in wheat in this district as required by your endorsement, No. 377, dated 28th ultimo, on G. O., No. 327, dated 5th ultimo.

2. I append a memorandum on the subject kindly supplied to me by General Morgan who perhaps knows more about agriculture than any other gentleman on the Hills.

3. He thinks rust is not common here or in the plains, but says that it is sometimes found where the soil is damp and stiff, and if the weather is wet and cloudy. He considers that neither mustard nor the wild barberry have anything to do with the disease. He says it may be prevented by pickling the seed-grain in a solution of sulphate of iron, a remedy found effectual also in the case of coffee-leaf disease; and adds (in opposition to Mr. Carruthers) that it is more common with some kinds of wheat than with others.

4. According to inquiries made from native cultivators it seems that—

(1) Damp weather and damp soils are conditions precedent to rust in every case and that the disease is much more common than General Morgan believes. They call it "Sarvamari noyi."

(2) Rust has not been observed to be more common in wheat grown near Mustard or the Barberry, of which latter two kinds are very common on the Hills—(a) the *Berberis Leschenaultii* or Nilgiri holly which grows on the edges of the evergreen sholas, and (b) *Berberis Asiatica*, very common all over the district in the neighbourhood of cultivation.

(3) The affected grain is covered with a grey ash-like appearance, and when squeezed, is said to leave on the hand a gummy white deposit "like the blood of worms."

(4) Some say that the ashes of cow-dung sprinkled over the grain is said to be efficacious in checking disease; others, however, know of no remedy.

5. I regret, owing to the receipt of your reminder on the 10th instant or days after receipt of the original order, I have not been able to make more extensive or satisfactory inquiries into this somewhat abstruse subject.

Memorandum from Major-General R. H. MORGAN, Ootacamund, 4th April 1883.

1. Some kinds of wheat rust more than others.

2. To prevent rust, pickle the wheat seed for 24 hours before sowing; one of the best pickles is a sulphate of iron solution.

3. The cause of rust is generally an undrained stiff clay soil, coupled with damp and cloudy weather.

4. There is but little rust in wheat on these hills or in the low country as far as I have seen.

5. I should say, so far as my experience goes, that mustard has no more to do with rust than has the barberry.

6. Rust is not only in the straw but in the grain: hence the necessity of soaking the grain in a strong pickle.

7. The coffee-leaf disease has also been propagated by seed. The only way to destroy the fungus is to soak the seed in a pickle.

8. Barberry bushes are very common in the vicinity of Burgher fields, but I have not noticed rust in the wheat.

SELECTIONS.

AGRICULTURAL SCHOOLS IN THE WESTERN TROPICS.

THE consideration we have of late given to the encouragement of new industries in the colony has, in a measure, been the means of directing our attention to the necessity of establishing a School of Agriculture. There is little good in telling even the more intelligent of the small landowners and labourers that they can, by cultivating the many and various products this colony is blessed with, make for themselves and their children, not only an easy livelihood, but an ever-increasing source of wealth and comfort. The fruits they know and understand, which grow, we may say spontaneously, requiring but little care and attention, they will, no doubt—a suitable market offering—cultivate and attend to in the manner their forefathers did before them. But we all know what an unsatisfactory system this has been. No care taken in the collection of plants, no attempt made, by grafting or otherwise, to improve those already known to all, and no trial given to new varieties. As were the fruits of British Guiana—with the exception of a few plants got from India, Jamaica, and Trinidad, by the proprietors of one or two sugar estates—so are they still, and with this serious drawback—the natural deterioration due to old and worn out trees, and continuously planting from the same class of seeds. The consequence is, our oranges are stringy, our limes are reduced to a size not much bigger than a walnut, and other plants have degenerated in like proportion. In fact, it is the unanimous verdict of all old colonists that none of the fruits of the colony have one-half of the excellence they possessed in their younger days. The reason for this is not far to seek. The cultivators, few though these be, know nothing of the good results to be obtained from grafting or from change of seed, and have accordingly been satisfied to go along in the old grooves.

An ounce of example is worth many pounds of precept, and fortunately for the colony and its future well-being, that example can now be obtained. In the Botanical Gardens, under the able administration of Mr. Jenman and his co-adjutor, Mr. Waby, colonists have an opportunity afforded them of witnessing the results that can be procured from scientific cultivation. The difficulty that presents itself to our mind, however, is that due advantage will not be taken of the opportunities thus afforded them, by farmers and small landowners, who seek more particularly benefit from the study of the work in the gardens. It is hard to move them off the beaten track, and we fear the gardens to them will only be a name. Were a School of Agriculture associated with them this would not long remain so. Our creoles, no matter of what colour or race, are not wanting in eagerness or adaptability; and parents, aware of the good they would derive from their children attending such a school as that indicated, would, we feel certain, gladly send their larger boys there. The example which would be set them of continuous industry, and the knowledge they would obtain of plant life—its conditions and proper mode of treatment—could not but have the very best effect on the agriculture of the colony. That this is true has already been shown by the advancement which has, within the last few years, been made by several of the villages in cane cultivation. The fields cultivated there are, in the great majority of instances, quite as well tilled and maintained—the item of manure only excepted—as any on the best sugar estates, and the return per acre has been good accordingly. Here we have a notable instance of the force of example, and it is but a natural deduction to add that, given a like pattern, like results would follow in other directions.

The Botanical Gardens are being, presumably, formed for the agricultural development of the colony, and for its ultimate benefit. Before they are completed three or four hundred thousand dollars will have been expended on them, and from what we have seen we have no doubt that amount will have been spent judiciously. But when we consider the intelligence of the vast majority of the taxpayers who have contributed unmurmuringly to this large outlay, we are inclined to ask *oui bene*? Only a few hundred of the inhabitants are intelligent enough to take advantage of lessons being taught them, or to appreciate the results to be derived from them. Without an Agricultural School in connection with the gardens, the colony, taken as a whole, will for many many years to come derive no recompense from the expenditure. But given the school—the pupils, we maintain, would shortly be forthcoming—their benefits would be open to all, and the lessons they are meant to teach would be, in a few years' time, spread through the length and breadth of the colony. Large reductions have this year been made in the estimates for education, and this because the Governor and members of the Combined Court considered there was no adequate

results being obtained for the money expended. In this we have no doubt they were right. In a purely agricultural colony such as this is, we want the children to grow up to be useful members of the community, and this is the end that should be aimed at in their early training. Our children must be taught that all cannot be "preachers, teachers, or stump orators." Agriculture is our sole maintenance, and the teaching given to the children should be such as would contribute to its advancement. The establishment of an Agricultural School would gradually have the way to this desirable end, and to no better purpose could a portion of the savings which has been effected in our educational system be devoted, than in founding a public school for instruction in purely Agricultural affairs.

The thousands of people who visited the Botanic Gardens yesterday afternoon were struck with the vast improvement which has lately been effected in their appearance, and the more intelligent amongst them were keenly alive to the value of work which had been, and was being, done; and showed an eager inquisitiveness as to the names and nature of the various plants. The warm interest they took in these things shows that the plan we urged a few months ago, of establishing an Agricultural School in connection with the Garden, would be a perfect success; and its benefits would be highly appreciated by the better-to-do portion of the working classes. In many of the purely agricultural dependencies of the British Crown, these schools are already successfully established, and we can see no reason why, if the idea was properly taken up by the Government, a like success should not attend their establishment here. In Jamaica, for instance, quoting from Mr. Morris's report, referred to last week, although an actual School of Agriculture has not been established, still a system of employing cadets, and apprentices, under the trained managers and superintendents of the Government plantations has been begun, and with the happiest results. He reports that the cadets, who are received without salary for the purpose of being taught the details of the cinchona cultivation, and with the view of fitting them either to open plantations on their own account, or to act as managers of cinchona plantations, are "devoting themselves with zeal and energy to their work, and taking a keen interest in all that concerns the value and management of labor; details of nursery work; the minutiae of planting; and the various methods adopted for successfully harvesting cinchona bark. The knowledge and experience thus gained will doubtless prove of great service to them in after-life, and I look forward to a great impetus being given to cinchona planting by the introduction of men of capital and education, who intend to devote themselves to this important industry."

Mr. Morris is quite aware of the fact that the plantations in Jamaica are being worked for the future benefit of the island, and he knows full well that the lessons he is striving to teach by lectures and pamphlets, will be still more effectually taught by the practical training of the young. Hence the encouragement he holds out to the sons of men of some capital to attend at the plantations and learn the details of their working. But he does not restrict himself to cadets only. He is quite well aware that skilled guides also require the assistance of skilled laborers, and he has accordingly engaged a number of apprentices "in order to train the better class of native workmen in the details of nursery and propagating work connected with cinchona cultivation, where they undergo a systematic course, so as to fit them in due time to take charge of nurseries or act as foremen on private plantations. The experiment, so far, has worked satisfactorily. The apprentices for the first three months receive only a nominal rate of pay, which however is gradually increased as they become more efficient. When applications are received for men to take charge of nurseries on private plantations, the best of these are recommended." Such is the system Mr. Morris is pursuing in Jamaica, and who can doubt that it will be highly beneficial to the colony, as well as to the large class of young men it is specially designed to benefit, and who have been without the means of lucrative employment.

If an Agricultural School is ever to be started in the colony, now is the time to commence it. A large portion of the Botanic Gardens is still unenclosed, and the lessons taught to students there now are much more valuable than these would be when the gardens are completed, and initiatory work finished. The cultivation of the smaller industries which the gardens are specially designed to encourage must first be undertaken on land in much the same condition, viz., undrained and abandoned. To put these in a fit state for the reception of young plants must be important work, requiring special knowledge, and that could never be better explained than by the practical illustrations the boys or others would now receive at the hands of Mr. Jenman. In Canada, Australia, some parts of India, Ceylon, &c., these schools under thoroughly practical trainers are doing a great deal of good. It seems rather an anomaly here, when compared with other colonies, that the only section of the community being deliberately trained to agricultural pursuits are those juveniles who qualify themselves by some grave offence against the law for a lengthened period of confinement and teaching at the industrial school at Onderdonk. In some respects, therefore, the lot of these is preferable to the law-abiding boys who do nothing but play marbles, or fly kites until they reach man's estates. This subject is an important one, and well worthy the careful consideration of all parties.—*Royal Gazette, British Guiana.*

DR. AITKEN ON TURNIP MANURES.

DR. AITKEN, who had attended the meeting at the request of the Galwater club, delivered a lecture on of "Turnip Manures." It was now 120 years since Dawson, of

Frogden, introduced the turnip to this country, and its cultivation had been rapidly developed. Among its advantages were that, when once grown, it could be stored, and afforded an independent food for cattle; it enabled the land to be much better cleaned; and it obviated what was a very ruinous kind of agriculture, bare fallow. The turnip crop had, however, its disadvantages also, and these were being experienced more now than in the early period of its history even long after the turnips were sown, there was still a considerable fallow break, which only few lands could stand, as it had the effect of decreasing the organic matter in the soil, and that is an important constituent. It was also a very expensive crop, even though useful for succeeding crops of cereals, and it was becoming year after year more liable to attack from disease. Turnips were not so much needed as formerly; they were too much grown nowadays, and in many cases on land which was better suited for pasture. Still they were a very important esculent, and would continue to be so. The question they had to consider was—What is the best kind of manure for turnips? Although we had grown turnips for upwards of 100 years, the fact that we were still asking that question showed that there were conditions to be fulfilled which made it very difficult to answer. It was a wide subject, and we were far from having anything like a definite idea of a special manure for a certain crop, a great deal depending on the soil and climate, by which the character of the manure was determined. It was thought that if the crop were analyzed, and its constituents ascertained, they would then arrive at the best manure for turnips; but that was a most erroneous idea. If they analyzed the turnip ash, it would give a great deal of sulphuric acid, an extraordinary amount of potash, much nitrogen, and comparatively little phosphoric acid. The plant assimilated most easily that which there was an abundance of, but what was wanted was to enable it to take up that which it had most difficulty in doing. He found manures being put forward in the market for turnips, whose great recommendation was that they contained a large amount of sulphuric acid. That was a case in point, where manufacturers were working on a wrong principle, and were putting into the manure that which the plant required least. To grow turnips properly they must, in the first place, have suitable land, which should be free, porous, warm, deep, and strong—not stiff, and the situation should not be too steep. They had next to consider the available nourishment in the soil, which would depend on the manner in which it had been cultivated and manured. Farmyard manure was very rich in potash, and poor in phosphorus and nitrogen; while bones were rich in phosphates, poor in nitrogen, and contained almost no potash. In the case of turnips on land to which farmyard manure was applied, the probability was that no potash would be required, as there was plenty in the manure; but if bones were being used, the addition of potash would in all probability increase the crop. The system of cultivating the turnip was very severe on the young plant. The seed was sown so thick that it had to struggle with its neighbour for existence; and in the process of thinning and hoeing, its roots were further interfered with, the only roots left in undisturbed possession of their original ground being those which had grown straight down into the soil. They had next to consider the kind of tillage, and they must not apply manures if they were easily washed away. Turnips grow for a period of six or eight months, so that they must be guided by the consideration that they may apply manures which will take some time to dissolve, but which the plants are sure to get later on. They had learned a good deal about turnips through the experiments carried on under the Highland and Agricultural Society. Phosphoric acid in some form was most essential. It was the constituent whose want was first felt in the ground, for almost all the other crops of the farm carried off phosphates largely, leaving very little behind for the turnip. Although there was great diversity of opinion as to the best form of phosphates to apply, dissolved phosphates were, as a rule, quickest and surest; but as the turnip took a long time to grow, it was able to make use of insoluble phosphates better than other plants of quicker growth, and certain kinds of land were specially suited for these phosphates. Moorland, or land rich in organic matter, possessed the conditions for dissolving phosphates, and on such lands insoluble phosphates were found very beneficial to the turnip crop. On clay land, on the other hand, insoluble phosphates had proved a failure, and superphosphate was there required. One peculiarity brought out by the Highland Society's experiments was that superphosphate produced a larger, even, and ripper crop than insoluble phosphates. The insoluble phosphates supplied in the market varied so much that one could never be sure of getting the best kind, but with superphosphate there was greater security. All kinds of the latter were of equal value to the farmer, no matter what their source might have been. Nitrogen also existed in several forms, but the most soluble was nitrate of soda, which was a rich and powerful manure. It required to be used with great caution, being easily lost, and it was wasteful to apply it before the plants were present to receive it. There were other nitrogenous manures, however, which could be applied as soon as desired, such as bones, which took a long time to decompose. Dried blood was another form of nitrogenous manure which was very rich, and it would lie for a month or two before being useful to the plant. Putting in a slowly dissolving manure along with the seed, meant that the plant would not get it until it had arrived at a certain stage of maturity, but it was necessary to apply also some more quickly-acting manure such as nitrate of soda. Potash, when applied to turnips along with farmyard manure, so far from having done the crop good, had actually done it harm; but when applied with bones it did good. He was therefore in favour of withholding potash from the turnip manure, and applying it for the cereal crops after the root crop

is off the ground. All kinds of compost were excellent preparations for the turnip, not so much for the sake of the actual food which the turnip required, but because they prepared the land for the delicate roots of the plant. There was not much doubt that a good crop of turnips could be grown from farmyard manure; but a more reasonable question to ask was if such a valuable manure was used to the farmer's best advantage in applying it to turnips? Perhaps the best way of economizing farmyard manure was to put it first on grass, so that its valuable nitrogenous constituents might not be lost, and then to spread on the fallow. Fodding stock on the land was, perhaps, the most economical and thorough method of treating the land, so as to improve its heart and texture, but some might think it rather slow. In concluding, Dr. Atken said the average turnip manure contained 20 per cent of soluble superphosphate, 10 per cent insoluble, 3 per cent ammonia, and, perhaps, potash also. The farmer could, however, determine his special wants by a very simple experiment. Having ascertained the relative need of his soil for phosphates, ammonia, and potash respectively, he could easily satisfy himself in what form each of those three constituents was most advantageously applied. He intended this year carrying on a set of experiments as before, but with a seven-plot instead of a five-plot test. Plot No. 1 will be manured with phosphates; No. 2, phosphates and potash; No. 3, phosphates, potash, and ammonia; No. 4, ammonia and potash; No. 5, ammonia only; No. 6, phosphates and ammonia; and No. 7 will get nothing. He had prepared schedules with instructions, and he would be glad to supply them to any one who would be willing to make the experiment, which could be done at almost no cost. He thought the Galawater Club should make a fresh start in that direction.

CULTIVATION OF THE POPPY IN ROUMELIA.

H. M. CONSUL at Salonica mentions in his last report that there are few industries in European Turkey, certainly none in Roumelia, that have been so successfully introduced and prosecuted as the cultivation of the poppy. The first attempt to grow the plant in the province of Roumelia was made about seventeen years ago, by a Turkish farmer at Istip, with a handful of the poppy seed, which he had brought from Kara-hissar, in Asia Minor; the experiment proved a complete success, and was renewed on a larger scale in the following year, 1866, since which the production of opium has annually increased and flourished in Istip, and the adjoining districts of Radovitz, Kotehan, Stroumitza, Tikvish, and Klaprula-Veles. The Roumelian opium, especially that produced in the district of Istip, is very pure, and contains about 11 per cent of morphia, while that of Smyrna contains scarcely 9 per cent, and is considered equal to the Malatia produce. In the year 1882, the production of the province amounted to about 135,000 lbs. of opium and 5,600,000 lbs. of poppy seed, most of the drug being exported to England, and about 4,000,000 lbs. of the seed being exported from Salonica chiefly to Germany and France. The Turkish Government, with a view to encourage the development of this industry, remits the tithes on opium and poppy seed for one year, in the case of lands that are sown for the first time with poppy seed, and distributes in the agricultural districts printed instruction on the process of cultivating the poppy, and extracting and preparing the drug from the juice. It appears from these instructions that the *khash-kash*, or poppy seed, is sown from the month of September up to March, in localities where there is no hoar frost in spring autumn but in places where there is hoar frost, the seed must be sown in the month of September, and in the spring, after the chilly weather is passed. The soil selected is generally light, rich, and yielding; if the seed is sown in cold, clayey soil, or in damp localities, the yield will be small, and the opium of an inferior quality. The ground is always well manured, and experience has proved that if a field which has just yielded a crop of opium be immediately sown with wheat, the crop resulting from this last sowing will be remarkably good. The soil of a field to be sown with poppy seed is ploughed two or three times, and well broken up. The seed is then scattered about with the hand; after this, the soil is again thoroughly stirred up and mixed by a rake, or a row of bushes bound on to the back of a harrow. As soon as the young poppy plants begin to appear above the surface of the soil, and to bear three or four leaves, in places where they are too close together they are taken up, and planted again in such a manner as to have a space of a span between each plant, and the soil hood two or three times to remove any weeds that may appear. Opium being a substance which is extracted from the pods or outer shells of the poppies, as soon as these pods become green in colour, and have reached their full growth, the green hue changes to yellow. A few days before this change of colour takes place, there forms over the pods a thin watery film of a light green hue; this film is called *cougak*. If it be wiped away with the finger its place still remains visible, and if at this time the pod be squeezed between the finger and thumb, it becomes so far strengthened that it cannot be easily crushed. It is at this time that the juice which forms the opium is gathered. In order to gather the juice or paste, an incision is made in the pod, beginning from the middle and going round the edges, at the same time leaving a space of about a finger's breadth, with a knife made expressly for the purpose, being small and sharp-pointed. Immediately this cut is made, there appears a white milky fluid of a bitter taste. This fluid gradually increases in consistency, and its colour becomes darker, until, in twenty-four hours, it is coffee-coloured, and as thick as paste. This is scraped off with the edge of a somewhat large and blunt knife, and put into a poppy leaf, and this is done until about twenty or thirty drachms of opium have been collected on one leaf, the edges of which

are then turned in so as to prevent it being spilled. If while the opium is being collected, the film be mixed with it, it has a beneficial effect. The work of cutting lines in the pods of the poppies is generally commenced early in the afternoon, and continued until nightfall. As the opium must be collected twenty-four hours after this operation has been concluded, the labourers commence on the following day, soon after twelve o'clock, to collect the opium from the pods which were cut the day before, and also to make incisions in other pods. Any pods which are not quite ripe, are left until they become thoroughly ripe and fit for cutting. In order that the exact season for collecting the juice may not be missed, the whole work must be performed in eight or ten days, and the proper time for marking the pods must be accurately ascertained, for if the pods be cut before or after they are quite ripe, there is no yield of opium. Great care is taken not to cut the pods while a high wind is blowing, or when it is raining, as in the latter case the rain washes away and destroys the juice as fast as it exudes from the seams that have been cut for it. After the opium crop has been gathered in, the pods change their previous hue, of either green or yellow, to rose colour; when this change takes place, the plants are taken up by the roots, one by one, and collected in small bundles. Each bundle is then bound by a young green wither, and so placed upright in the ground that the roots of the plants are covered, in which position they remain for a few days, until the seed contained in the pods becomes thoroughly dried and matured. The pods are then threshed with a stick until they break open, when the seed is collected. Another method which is often employed, is to sever the stem of the plant at the knot which is found close up to the pod with the finger and thumb, and after collecting the ends so severed, to spread them out to dry in some open place, and then to break them open by threshing, or else to pull them to pieces, and after sifting the seed until it is quite free from extraneous matter, to collect it. At Kara-hissar, most of the pods are burned to reduce them to ashes, and a fluid is extracted from them, which is used to bleach cotton, as it is considered more effective than the water which is strained off from ordinary ashes. After extracting the oil from the poppy seed, there remains a sediment technically called *kynube*, on which buffaloes, cows, and black kine generally, are fed, on the ground that such diet increases the amount of milk given.—*Journal of the Society of Arts.*

TIMBER FOR TEA BOXES.

ONE of the great benefits which railway extension, when completed, will confer on the rising tea industry of Ceylon, will be that of placing suitable timber, cheap, while sufficiently durable, at the disposal of planters. Boxes of proper sizes can be transported in shooks, the parts so prepared that only putting together, hooping and nailing, will be required. An establishment purchasing, seasoning and working up large quantities of cheap timber ought, it appears to us, even now to be able to supply boxes in shooks, which after bearing railway, cart and coolie carriage, would be cheaper than those made on estates by ordinary carpenters. In any case such boxes ought to be less liable to warp, and so better suited to be easily and rapidly put together. Premising that some estates may be entirely destitute of timber, the whole question in the case of properties possessed of reserves must be one of cost: the fact being kept in mind that the market value of reserve timber ought to be approximately calculated. Wishing to have reliable data for comparison between estate-made boxes and those obtainable in Colombo, we have been making personal enquiries. In one case we found that *hal* and *mango* timbers were employed. Against the latter there is a good deal of prejudice owing to the supposed acid quality of its juices, while *hal*, unless very carefully seasoned, would also be objectionable. The price quoted for an 80 lb. box was Rs. 1.80, with 5 per cent discount for a quantity. At another establishment we were shown some well-seasoned *lunumedilla* timber which in appearance and texture seemed all that could be desired. Our only fear was that this really nice-looking timber was open to the same objection as the white and red cedars of India, that of being too good for the purpose. For it is not part of the function of the tea planter in India or Ceylon to supply the buyer of his tea with timber which can be advantageously utilized in England, unless he is certain of a price being bid high in proportion to the value of the timber and its cost to himself. If the boxes are made of well-seasoned timber, free from corrosive juice or offensive odour, not liable to attacks of dry-rot or insects, and able for a period of four months or so to resist exposure and knocking about, that is all which can be desiderated. The price quoted for an 80 lb. box of this really superior timber was Rs. 2.12, thirty-two cents, or nearly one-third of a rupee, dearer than the previous quotation. We cannot help hoping, however, that *lunumedilla* can ultimately be obtained at prices which will lead to its utilization for tea boxes. It grows rapidly to a great height and sends out so few horizontal branches that a very large number of trees could be grown on an acre of land. As the tree is said to be fit for timber purposes in its tenth year, it seems obvious that plantations of this fast-growing timber-tree ought to pay well by and by. Mr. W. Ferguson, with all his study of trees and their properties, is of opinion that of all the timber trees of Ceylon this is the best suited for the manufacture of tea boxes; but it is so useful for many purposes, especially of boat-building and house construction (it makes beautiful ceilings), that we fear it is too expensive to be converted into tea boxes. As there is not much spare capital in the island, and few persons who can afford to wait ten years even for a large return for their money, we commend the cultivation of this tree emphatically to the attention of the Forest

officers of Ceylon. The tree is especially a free seeder, so that hundreds of bushels of the seeds could be obtained at once. An allied tree, what in Ceylon we call popularly "the Persian lilac" (from its sweet-smelling lilac-like blossoms) has the same property of producing a large crop of seeds. We saw a specimen in Mr. James Healy's grounds at Kew, a suburb of Melbourne, and found that it was known in Australia as the "white cedar." We have never heard of its attaining the dimensions of a timber tree in Ceylon, but it ought to be more prized than it is as an ornamental dwarf-tree. Mr. Brace, who wrote an essay on tea cultivation, which was published at the *Observer* office, gave a list of a dozen and-a-half timbers which he knew or supposed would be suitable, and noticed the *lunumedilla* thus:—"Melia composita. Probably an excellent wood for this purpose. Beddome remarks:—"It is common in Ceylon, and is known by the native name of *lunumedilla*, and Mr. W. Ferguson of the island says the timber is very light and cedar-like, and in use for outriggers of boats and ceilings, and that it is said whiteants will not attack it. This probably might take the place of our cedars, not only for boxes, but for most of the items of furniture needed on an estate." Mr. W. Ferguson now writes:—

Kal is so inferior and so full of resin that it is only used for coffins. *Mango* wood is considered an inferior wood, but has been a good deal used for coffee casks.

The *lunumedilla* is no doubt about the best tree and timber for tea-boxes in every respect in Ceylon. It is of very rapid growth, is still an abundant tree in the island, easily procurable, being floated down the rivers. It is used for the outriggers of Ceylon canoes; for kattumarams; is the best Ceylon wood for ceilings because it has a slight look of mahogany and can be varnished or polished, and is said not to be attacked by whiteants; is very light but not strong, seasons very rapidly. It was described under several botanical names and generally as the *Melia composita* of Willdenow, but Mr. P. Hiern, who has worked out this order in *Flora Brit. Ind.* 1, p. 545, restores its first or oldest name, *Melia dubia*, Cavendish, and gives the following synonyms for it:—*M. superba*, Rox., *M. robusta*, Rox., *M. australasica*, A.D. Juss., *M. sethiopia*, Welw., *M. Bombolo*, Welw., and *M. argentea*, Hb. Ham. I feel sure that it is also the *Auletia javanica*, Gaert. 1, 277, t. 58, f. 2.

Seeds about the size of an olive, and very like them; can be had in abundance in their season. Tree very high, leaves tripinnate very large, on tops of branches, not a good shade tree, because it is quite leafless at times.

I saw an advertisement in the *Observer* from the Madras Railway or Harbour Department some months ago, calling for tenders for a supply of this wood, as *Malay Vambu*, if I recollect aright.

Mr. W. Ferguson and others will, however, like ourselves, have to review their opinions in regard to *Kal*, in the presence of a specimen box of this wood sent to us by the manager of the Ceylon Company, Limited. This Company has had its experience of bad as well as good woods, and the final conclusion is in favour of good, well-seasoned *Kal* for tea-boxes. This was intimated to us in answer to a letter of enquiry whether materials for tea-boxes procured and prepared in quantity could not be sold at a price cheaper than the cost of boxes in many cases made on estates. Copy of a circular was sent to us, in which we were told we should find our suggestions anticipated. In this circular, amongst information in regard to the leading requisites for packing tea, we find the following:—

TEA CHESTS.—The company have a large stock of thoroughly seasoned *Kal* wood cut up for chests, only requiring to be put together.—The chests are dovetailed, and their outside measurement is 24 in. by 19 by 19 in., so that ten chests make exactly 1 ton of 50 feet cubic measurement.

They hold 85 lb. Pekoe Souchong,
90 lb. pekoe,
110 lb. Broken Pekoe,

and can be supplied in shoeks delivered at the Colombo Railway Station at Rs. 1'30 each (without nails), or made up (with nails) at Rs. 1'40 each.

A chest requires about 70 to 80 wire nails (1 lb. = about 380 nails.)
" " 6 lb. tea lead.
" " 3 oz. solder.
" not quite 1 lb. hoop iron.
" about 70 rose nails for fastening do. (1 lb. = about 560 nails.)

Now, provided the *Kal* wood tea chest turns out to be good and serviceable,—and we can affirm that it looks the right thing, while the Company's Manager says the chests made of *Kal* are good and compare most favourably with Indian tea boxes, of which a large number has passed through his hands, we have here a box of superior capacity at a lower price than those previously quoted (made up with nails Rs. 1'40 each) and constructed on such scientific principles as to size, that ten such boxes make up exactly the measurement ton of 50 cubic feet by which freight on tea is charged. If, in addition, the Company could manage so that each box should weigh exactly the same, so as to save the injurious necessity of bulking in the London Customs, they would deserve to be regarded as special benefactors to the tea interest of Ceylon. Perfectly seasoned wood, if not exposed to wet, ought not to alter appreciably in weight, and the weight of nails, tea lead, solder and hoop iron should be uniform. We surely are within hailing distance of the time when the quantity of tea of each kind in boxes can be so entirely relied upon, even by men so accustomed to the shifty side of human nature as customs officers, that there may be no occasion to open boxes before sales, except for the purpose of taking samples.

All tea planters are grateful for having the above information placed prominently before them, the best way in which they can

make a return is by supplying us, for the benefit of those interested in the new industry, with information as to the kinds of forest trees, in the low country and at high elevations, which have hitherto been found best suited for the boxes, the prevalence of such timbers, and the comparative cost at which they can be felled, sawn, seasoned, and worked up on estates. It is of much importance that the use of tea driers will save the necessity of converting some of the best timber on estates into charcoal, because such timber can now be utilized for tea boxes or other purposes. With railway extension, indeed, it is possible that coke may be found a cheaper and better fuel for the tea-driers than firewood, the smoke from which might be objectionable. As the supply of really good timber in the hill forests of Ceylon is, after all, very scanty, information regarding the best trees to grow at various elevations will be valuable. We do not forget the lists of low and high elevation trees issued by the late Dr. Thwaites, but they were prepared without any reference to the question now being discussed. We fear the *lunumedilla* is specially a low-country plant, but probably trials will show that this and other suitable plants have a pretty extensive range as regards altitude.

Our present enquiries were started by the receipt of a letter from Mr. J. S. Gamble, whom we had the pleasure of meeting in British Sikhim in 1876, and who is now at the head of the Madras Government Forest Department. To the Indian and botanical names furnished by Mr. Gamble, Mr. W. Ferguson has, at our request, added notes indicating whether the trees are indigenous to or to be found in Ceylon. Here are the letter and the notes:—

Madras, April 3rd, 1883

SIR,—At p. 720 of your March No. of the *Tropical Agriculturist*, you take me to task for not giving the scientific names of the trees which I enumerated by their vernacular ones, as producing woods fit for tea-boxes. So I send you the list with the native names perfectly corrected as to spelling. The misprints were chiefly made by the *Indian Forester*, I see. For 'Chota Kaggur' please read 'Chota Nagpur.'

Yours,
J. S. GAMBLE.

Mr. W. Ferguson's Notes:—(a) Not a native of Ceylon. Introduced in Peradeniya. (b) Not in Ceylon. (c) Katu-Imbul. Red flowered silk-cotton tree. (d) Not in Ceylon. (e) Common Ceylon tree. (f) Not in Ceylon. Leguminosae. (g) In Ceylon hills rare. Dotiscaceae. (h, i, and j) Not in Ceylon. (k) Not in Ceylon. Bhootan, Sikhim, Eastern Himalaya. (l) Sikhim 5,000—7,000 ft. Martaban, Java. (m) Native of Northern India. (n) Also Northern India. (o) In northern part of Madras Presidency, and in Bengal; this and No. 4 closely allied. We have in Ceylon the *Kokuna*, *Canarium Zeylanicum*, Thwaites.

Mr. W. Ferguson adds detailed remarks as follows:—

NOTES ON MR. GAMBLE'S LIST OF TIMBER TREES FIT FOR TEA BOXES.

I have put notes opposite to Mr. Gamble's list, and I shall here refer to the Nos. only, as there is no use in repeating the native and botanic names:—

1.—Introduced to Ceylon and in the Peradeniya gardens. Same family, Meliaceae, as the *Lunumedilla*.

2.—Not yet in Ceylon. D. moluccana, in the Peradeniya gardens. See Morris's list. It is of the same family as the *Iagerstromia flos-regine*, the Muruta.

3.—The red flowered silk cotton tree. Kattu-Imbul. Wood too weak and perishable, I should think.

4.—The family that produce the aromatic gums of the Role. We have one in Ceylon, the *Kokuna*. C. zeylanicum, Thwaites. See No. 15 of same family. I don't think the timber of these would be good for tea boxes.

5.—Ceylon tree, large, and a quick grower. I know it well, but don't know much about its timber. It is so close an ally of the *Bak-mi*, which injured some Ceylon Company's tea, and about which Mr. Horsfall wrote to the *Observer*, that they used to be in the same genus, Rubiaceae.

6.—Not in Ceylon. An Indian tree. Don't know much about it. A large tree.

7.—A Ceylon tree. The only one of the order Datisacae. I have never seen the tree, and failed to get a specimen of it.

8.—Not in Ceylon. Several of the family in Ceylon. I do not think any of them will be good for tea boxes.

9.—None of this genus in Ceylon.

10.—Not yet in Ceylon.

11.—Not in Ceylon. Allied to the *Weralus*. Bhootan, Sikhim, Eastern Himalaya.

12.—Not in Ceylon. An obscure family. This tree 60 feet high: Sikhim at 5,000—7,000 feet. Martaban, Java.

13.—One of the laurels. Native of Northern India. Eudawulu, a famous timber tree on estates in Dimbala and elsewhere,

a close ally, but some of them are likely to have aromatic woods. The famous *Yaverri*, *Ascedaphne semicarpifolia*, of the Eastern Province. A good wood. Same family cinnamon, camphor, &c.

14.—Not in Ceylon. Northern India. Same family as No. 13.

15.—Not in Ceylon. In northern part of the Madras presidency and Bengal. See my note on No. 4.

See No. 13, p. 53, "Tea Cultivation in S. India and Ceylon," &c., and W. F.'s "Timber Trees."

As lightness combined with just sufficient strength to carry home a load of tea safely are the desiderata for tea-box timber, it is quite possible that experience may decide in favour of trees which the writer of the notes does not estimate highly. For instance, the *Bombax malabaricum*, or scarlet-flowered cotton tree. We do not know about its rapidity of growth, but such trees as this and *Erythrina indica*, and especially the common green cotton tree, could be crammed in great numbers into a limited space of ground. We do not want valuable timber for tea-boxes. If it is light, so much the better, provided it will season well and stand knocking about for a few months. Objectionable aroma, juices and gum, could probably be got rid of by judicious seasonings. Fire heat or steam, properly applied, can effect wonderful changes in the nature of timbers.

We add some general remarks with which Mr. W. Ferguson accompanied his notes:—

Surely by this time you and the other tea planters of Ceylon, viz., Taylor, Elphinstone, Armstrong, Jones, Blackwood, Ceylon Company, Owen, and others, have found out the cheapest and best kind of boxes, native or foreign, for packing tea in, and, if made of native woods, there ought to be a list of native names—at least of those found best fitted for the work. [Details regarding the timbers used on Abbotsford will be forthcoming immediately.—ED., C. O.] I do not think there is any use in attempting to introduce and grow any foreign tree for this purpose, as I believe we have abundance of trees which will answer equally well.

Mr. Owen sent me a list of trees some time ago, and asked me to say which of them were suitable for tea boxes. I met him in the *Observer* office, and said: "Trust a great deal to your native carpenters, who know the qualities of the different native woods. Don't use those that have milk, gum, or acrid juice, resin, &c., in the wood. Don't use heavy wood, nor one that will perish very soon, and don't let the wood have any smell of any kind, if possible."

But I fear the great bugbear is the want of proper seasoning in the log, and after it is sawn, before it is converted into tea boxes.

There was a regular set of saw-mills at work in the forests at Awisawella some time ago sawing timber for tea boxes and other purposes, and the gentleman in charge whom I met at Mr. Ward's house at Hanawella some time ago, promised to send me a list of the good and bad trees. I made a selection of 113 of the best timber trees of Ceylon, when I made the notes to Mendis's list, but I shall now include all the real trees of Ceylon, and finish their uses, or wipe them out as utterly useless. How in the meantime can we get lists from the different tea planters named, showing the best tea woods they have actually used?

We cannot doubt that the information desiderated will be supplied, so that ere long we may have a reliable list of the most suitable timbers for tea-boxes and all the purposes connected with the tea industry.

Meantime we quote from Mr. Brace's list:—

ACROCARPUS FRAXINIFOLIOS: RED CEDAR.—"The timber is flesh-coloured and shrinks in seasoning; it is light and much resembles that of *cedrela toona* and has a cedrelaceous smell; it is known to planters by the name of Shingle Tree, Pink Cedar, and Red Cedar, and is called *mullay* here in Jinnavelly, and *kilingi* by the burghers on the Neilgherries; it is of rapid growth and well worthy of cultivation by the Forest Department" (Bedd. Flor. Sylv.). I have used this timber more perhaps than any other for tea-boxes and tea house furniture in general, and if it has been well seasoned it is as good a wood as could be procured for the purpose. I am not aware if this tree is found in Ceylon, but as it is readily propagated from seed, I could suggest its being introduced. I cannot urge on planters too strongly the advisability of planting up odd corners of their grass-lands, &c., with useful timber trees, the cost of so doing is a mere trifle, and the addition made to the value of the property, say, in ten years' time, is very great.

ALSTONIA SCHOLARIS.—"In Ceylon it is called *rockattana*, and the wood is therefore generally employed for making coffins. * * * This wood, which is very bitter, is white and light, and is used for making packing cases, &c." (Bedd. Flor. Sylv.)

This would probably be found an excellent wood for making boxes.

ARTOCARPUS HIRSIUTUS.—"This tree yields the auley wood so well known on the Western Coast for house building, ships, frame-works, &c. The tree attains a large size in the forests on the Western Coast, where it abounds. The fruit is the size of a large orange, and abounds in a viscid juice, which freely flows from the rind if touched; this is manufactured into birdlime." (Drury, id.). This too is an excellent wood both for making boxes, buildings and estate furniture generally, and like its congeners as ornamental as it is useful.

ARTOCARPUS INTEGRIFOLIA.—"This is perhaps the best wood for box-making of any; and is easily propagated and of rapid growth.

Beddome remarks that this tree is only found in Ceylon. Probably the timber is very similar to that of the other varieties and might be used for the same purposes.

CEDELEA TOONA: WHITE CEDAR.—"Called on the Neilgherries *kai kilingi*. Drury remarks, "The wood is dense, hard, red, close-grained, capable of high polish, not subjected to worms, nor liable

to warp, and durable." Beddome says that "it is curiously absent from Ceylon." (Flor. Sylv.) This is a splendid wood, in my opinion, and as it is readily raised from seed and of rapid growth, I would strongly advise Ceylon planters to introduce it. I never use any other wood when I can procure this at a moderate rate. There is hardly a purpose to which it may not be supplied. I employ it for leaf racks, rolling tables, &c.

LITSEA ZEYLANICA.—"This tree is most abundant on the Neilgherries at 6,000 to 7,000 feet elevation, and is found throughout our Western Ghats at elevations about 2,000 feet, and is equally common in Ceylon where it is called *dasari korrendee*." (Bedd. Flor. Sylv.) This is perhaps the best wood when well seasoned for boxes that one can meet with at the higher elevations, quite equal to the red and white cedars.

MACHILUS MACRANTHA.—"Called in Ceylon *ullala*; the timber is often used for building purposes: it is light and even grained, and would answer as a substitute for deal." (Bedd. Flor. Sylv.) This is probably a first-class wood for box-making.

TECTONA GRANDIS: TEAK.—"Teak is an excellent wood for boxes when it has been well seasoned, and can be procured cheap. Though heavy, it can safely be sawn much thinner than other woods. I am not aware if the tree is found in Ceylon.

TERMINALIA BELLERICA.—"Found in Ceylon and there called *bulu*. It answers well for packing cases and coffee boxes." (Bedd. Flor. Zeylan.). This would probably answer well for tea-boxes also.

It would thus appear that there are trees indigenous to Southern India, which would be valuable if they could be naturalized in Ceylon. The jack tree and the del (*Artocarpus nobilis*) are, of course, too valuable for tea chests. So we should say of teak, unless it could be obtained in abundance and sawn into very thin laminae. If Mr. Brace is correct, the *dasari korrendee* ought to be found useful at high elevations. But the railway is a great leveller, even of altitudes, and the time is probably coming when nearly all tea estates will be supplied with tea-boxes from the "low country." A correspondent of the local *Timber* writes as follows:—

"The owners of tea estates would do well to begin at once the growing of suitable timber trees, as it will greatly enhance the value of their properties. Even where there is a forest reserve, it is chiefly valuable for its fuel, as the suitable timber trees form but a very small percentage of the forest. There are numerous kinds of indigenous fast-growing timber trees that would thrive better than the Australian gums on high estates. Jack is too heavy a wood and is not of very quick growth. Teak is as heavy, but is a harder and better timber for chests, if sawn in thin pieces, and exposed for a few months in a dry place or shed. It grows faster than jack after the first year. *Hallimilla*, *Boramel*, *Suriyah* (tulip tree), *Catta imbul* are very suitable, and are very fast growers. The tulip tree wood is little used, being scarce, as all is bought up by carriage builders. It is light, strong, pliant and suited for tea chests, being free of resin and acids, &c. On some coffee estates, where no timber trees are grown, fuel for coolies has to be bought and carted to the estates, and doled out pound by pound. This will occur on tea properties when the reserves are exhausted, or planted up, as they will be, when the old clearings look seedy. For many more reasons the early planting of timber trees is a necessity on tea estates, and they who have omitted to do so should begin at once.—*Ceylon Observer*."

WHEAT MILDEW.

(BY WILLIAM CARRUTHERS, F.R.S., Consulting Botanist to the Royal Agricultural Society of England.)

[Extract from the Society's Journal.]

THE minute fungi which live on other plants, and produce blights or diseases, have received special attention in recent years, because of the serious losses which they bring with them, and because of the remarkable facts in the economy of vegetable life which their study has disclosed.

The hop, the vine, the potato, and the different cereal crops are equally liable to great injury, and sometimes to destruction, from the attacks of these parasitic plants. And none is more wide-spreading in its attack, and more serious in its action, than the mildew which attacks the wheat crop in summer or autumn.

The desire to discover some means of preventing or alleviating the malady caused by mildew, has led to the frequent careful study of this plant. In the second volume of this journal (pages 11 and 226), Professor Henslow, in a paper on the diseases of wheat, gave a careful description of the mildew, and reasons for believing that rust and mildew were produced by the same fungus. He also investigated the prevalent notion that the barberry was in some way connected with the mildew, and recommended that experiments should be instituted with the view of testing the matter. He was not himself prepared to accept the opinion, though he records a case which he found it hard by any other explanation to understand. A farmer in Oxfordshire had a field which, when sown with wheat, was generally infected at one portion with mildew. This part was in the immediate neighbourhood of an old hedge, in which there were several barberry bushes. The blight did not extend farther than twenty yards from the hedge, and it was most abundant in the immediate neighbourhood of each of the somewhat widely-separated bushes. The farmer had all the barberry cut out of the hedge. He took one of the largest bushes, and placed it in the middle of the field. Before reaping he found the straw, for some yards round the bush, injured

by mildew, though not to the same extent as on the side of the field high to the hedge.

A later volume of the journal contains an able and lucid exposition of the parasitic fungi of the British farm, which had been delivered as a popular lecture by the Rev. Edwin Sidney, and among them is included the mildew fungus.

Until the investigations of Tulasne and DeBary, nothing was added to the knowledge of the mildew beyond what was contained in these papers.

The beller held by Henslow, that rust and mildew were produced by the same fungus, was demonstrated to be the case by Tulasne, who proved that the rust was an earlier stage in the life-history of the plant which afterwards produced the mildew.

The relation between the barberry and the mildew was established still later by DeBary, who discovered that the cluster-cup or *Æcidium* on the leaf of the barberry was a still earlier state of the mildew than the rust.

That a plant might spend some stages of its life in conditions, and under a form different from its perfect state, was in harmony with obvious facts in the animal kingdom. The development of the grub living in the earth or swimming in the water, into a fly or beetle inhabiting the air, made one familiar with great changes in the life-history of an organic being. The perfect state was easily determined, and use only in that state had the animal the power of producing eggs, and so providing for the continuance of its kind. In the parasitic fungi, each stage ended in the production of spores—that is, of bodies equivalent in function to the seeds of flowering plants or the eggs of animals, and capable of developing fresh individuals.

The structure of the fungus in the different stages of its existence as the *Æcidium* on the barberry, and the rust or mildew on the wheat, was so very different, that botanists could not entertain the notion that any organic relation existed between them, and those most intimately acquainted with these parasitic plants were most decided in their views as to the absurdity of entertaining such a notion. Especially did it appear improbable that the plant grown from a spore should have no resemblance to the parent producing the spore, but that instead it should belong to a group which the scientific student had widely separated from the parent. Within the last ten years our first authority in England wrote:

"There has been a very unjust charge brought against *Æcidium berberidis*, a beautiful species which attacks the leaves, flowers, and young fruit of the barberry as if it were the cause of mildew in wheat. Great, however, as are the changes which fungi undergo occasionally in passing from one condition to another, there is not the slightest reason for imagining that the *Æcidium* is a transitional state of wheat mildew. It has its own mode of propagation and passes through nearly the same phases of vegetation as the mildew, without affording a suspicion that it is not a perfect plant. The whole story has no doubt arisen from the *Æcidium* being common on the barberry in hedges surrounding wheat fields; and there is reason to believe the report is true, that wheat has been especially mildewed in the neighbourhood of the *Æcidium*. The peculiar situation may, however, be equally favourable to either parasite; and it is to be observed that mildew is peculiarly prevalent in districts where the barberry is unknown except as a garden plant."

The careful investigations and experiments of DeBary, corroborated by the subsequent discovery by other botanists of similar phenomena in the life-history of other fungi than mildew of wheat, have, however, determined beyond all question that the *Æcidium* of the barberry, the rust and the mildew of wheat, are only stages in the life of the same plant, though each stage presents the phenomena we have been accustomed to consider characteristic of a perfect plant—the producing innumerable spores or seeds capable of giving rise to new individuals. DeBary has indeed produced each stage of the plant from the spores produced by the previous stage.

Let us now trace the history of the fungus through its different forms of life.

The first stage in its life, after the rest of the winter, is that which it passes on the barberry. In the spring the leaves of this plant may sometimes be found with swollen yellowish spots, which in a short time burst through the skin, and form little bordered cups filled with a reddish powder. Under this form the plant is known as *Æcidium berberidis*. The genus *Æcidium* was, till recently, believed to contain a clearly limited and natural group of species, of which nearly forty were found in Britain on the leaves or stems of the barberry, gooseberry, buttercup, anemone, spurge, nettle, &c.

That on the barberry occurs chiefly on the leaves, but sometimes attacks the leaf-stalk and the fruit. It may be detected in May or June as a bright red spot on the under-side of the leaf, which, when carefully examined, is found to be a little cup full of free, round, and very minute bodies. A still more minute examination of the leaf will show that the fungus has another form of fructification on the upper surface of the leaf, where one may detect some scarcely perceptible pustules, through the central pore of which protrude a small bunch of minute hairs. In section and under the microscope these pustules are seen to be the openings of small flask-shaped bodies filled with the delicate needle-like hairs which protrude themselves through the opening. Towards the base of the flask may be detected numerous very minute round bodies, the function of which has not yet been clearly ascertained. The larger cups opening on the lower surface of the leaf are found to be equally well defined, and to be enclosed in distinct covering. At first appearing as little spores, they increase in size until they burst through the skin, and the apex breaks in a more or less regular manner, forming a margin to the cup, which is filled with minute round bodies of a reddish colour. These are the spores from which the next stage of the plant is developed.

Both forms of fructification grow on very delicate fungal threads, called mycelium, which penetrate the leaf in every direction, and

withdraw from it the food required for the life and growth of the parasite.

The quantity of spores produced by the cups on a single barberry leaf is enormous. It is impossible to realise the myriads of fungal spores which are floating in the atmosphere during the greater part of the year, ready, whenever the fitting physical conditions are present, to germinate. No place is free from their presence. They are so minute that we see them only as motes dancing in the sunbeam. But though so minute, they are mighty agents for good or for evil, because of their extraordinary quantity.

The spores of fungi are limited to some extent in their operations by the fact that each spore can germinate only on the species of plant that is proper to it. If the seed of a flowering plant be supplied with suitable heat, moisture, and air, it will germinate in any soil, and maintain a vigorous life or otherwise, in accordance with the character of the soil. But happily the spores of these fungi must not only have the necessary physical conditions required by the seed, but they will fall in establishing themselves unless they further find these conditions associated with that particular species of plant with which their life-history is associated. Were it not so, the spores produced in a single season would be more than sufficient to clothe every inch of the surface of the earth with a dense mould.

The red spores of the barberry fungus will produce a mycelium only when they germinate on the leaf or stem of wheat, or of some other grass. And they can germinate there only when they can obtain a sufficient supply of moisture.

It is a very general notion that mildew and other blights are "in the air," or are produced by fogs or mists. To some extent these notions are true. The farmer has observed the atmospheric conditions favourable to the growth of the spores, and without being aware how they quickened into life the everywhere present spores, they give the physical conditions the credit of being the efficient producers of the blight. But just as dry grain remains for any length of time in the barn without germinating, so the spores of the potato-fungus rest on the potato, or those of the barberry-fungus on the wheat without germination, if there be no free moisture accessible to them. A slight reduction of temperature, when the warm air of summer or autumn is saturated with moisture after rain, liberates some of the aqueous vapour which had formed an invisible ingredient of the atmosphere, and a mist is produced. This mist supplies the spore with the moisture it needs, and germination begins; a small tube is pushed out, and finding its way to one of the minute openings or stomates of the leaf, it passes through into the tissues, where, finding suitable food, it rapidly grows. In a week or ten days one can detect the presence of the fungus in the wheat by linear reddish swellings on the leaf and stem. When ripe, the skin bursts, and innumerable oval red spores are exposed and dispersed.

When the suitable conditions are present, these spores germinate on wheat or on other grasses, the growing tubes pass through the stomates, produce mycelium in the cellular tissues of the leaf, and in a week, more or less, a new crop of spores bursts the skin of the plant, and is scattered in the air. Several generations of this form of the fungus may be produced in the course of a few weeks. In the older patches, and from the same mycelium, another kind of fruit is produced, at first among the red spores of the rust, and then entirely by itself when the production of the rust-spores ceases. These are the spores of the mildew. They are oblong, and taper towards each end, and are composed of two cells, the division being across the middle of the spore.

As in the rust, the delicate threads or mycelium of the mildew penetrate the cellular tissue of the leaf or stem in every direction.

The spores are produced under the skin. They form long narrow swellings of a brownish colour. When the swellings burst the skin, a mass of dark spores fills the opening. If the disease is very bad, the plant is so completely covered with the dark spores that it has the appearance of having been scorched.

The active life of the fungus closes with the production of the mildew-spores. These spores do not germinate and propagate the mildew on other wheat plants. This is done only by the spores of the rust. The mildew-spores remain on the leaves and straw throughout the winter, and show no signs of life till the spring, when, under favourable conditions, they begin to germinate. Each of the two cells of which the spore is composed sends out a short filament, that terminates in three or four branches. The tips of these branches swell, and another kind of spore is produced, after which the filament dies. These minute and delicate spores develop a mycelium only when they germinate on the leaf of the barberry. The germinating filament does not seek admission to the leaf through a stomate, but it has the power, like the spores of the fungus which causes the potato disease, of penetrating the skin where it germinates and passing directly into the tissues of the leaf. There it rapidly grows, and in a short time produces the two kinds of fructification which have been already described.

The injury done to the wheat by the rust and mildew arises from the fungus appropriating to its own use the elaborated juices of the wheat. Fungi are plants with out the green colouring matter or chlorophyll, which exists in other plants, and they are consequently unable to separate the carbon from the carbonic acid gas of the air—that is, to manufacture plant-food from the raw materials on which plants live. They therefore depend on the already prepared food of the plants on which they are parasitic. The fungus in its rust-stage takes possession of the growing plant, and weakens it so far as it appropriates material which was intended to build up the growing wheat. But as the wheat at the time of the attack is very active in assimilating food, the rust rarely injures to any serious extent the crop, unless in an exceptionally wet season, when the abundance of moisture secures the germination of successive crops of spores. A few bright sunny days arrest the progress of the fungus, and vigorous plants overcome the attack without any real injury.

When, however, the mildew appears at a later stage in the leaf of the wheat, the conditions are entirely changed. The period of active assimilation of food is past. The plant has laid up stores of food in various parts of its structure, and the processes of flowering and fruiting, which use up these stores, are proceeding. The altered starch is being conveyed from the cells, where it was temporarily located, to its final destination in the seed. The fungus arrests it in its progress, and converts it to its own use. The wheat is not able to cope with the parasite as in the earlier stage of its life when the fungus was present as rust. It cannot start again the process of assimilating food, and consequently the seed is more or less imperfectly filled, in proportion to the time at which the fungus attacks the plant, and the extent of the attack.

The story of the fungus suggests important considerations to the farmer. First, it is certain that the brown spores of the mildew which remain attached to the straw after harvest, are the means by which the fungus retains its vitality through the winter. Converting the straw into manure does not destroy the spores, but rather provides in the spring the conditions fitted for their germination. It may be recommending a serious destruction of property to suggest the burning of mildewed straw, but fire is the only agent that will effectually destroy the spores.

Then it should be noted that even the brown winter spore produced by the mildew will be harmless, unless the spores formed at the tips of its branches in the spring rest on the leaf of the barberry. The farmer should not permit the barberry to have a place in his hedge, or in plantations on his farm.

Further, that while rust may in itself be injurious to the crop, it is more dangerous at the earlier stage of the mildew, and as the producer of the crop of spores which produce mildew. The only check to the rust is a bright sun and a warm dry atmosphere.

From the history of the fungus it is manifest that at no stage is it under our control; and though we can take steps which may prevent at different stages the unnecessary increase of the spores, we must be baffled in any attempt to prevent the appearance of the disease, whether in the rust or the mildew stage.

I have never observed any variety of wheat that has escaped mildew at a time and in a district where mildew was prevalent. Sometimes one field may suffer less than another in the same district, and at the harvest may yield a heavier and better field-grain, but this I have found to result from the time at which the field was attacked by the disease. Some of the prepared food of the plant may have been stored in the seed before the parasitic robber interfered with its transmission. An early field may consequently suffer less. But when the atmospheric conditions have been present for the germination of the spores, I have failed to detect any difference in liability to blight, arising either from the variety of the wheat, or from the method of cultivation.

SULPHITE WOOD PULP PROCESSES.

THE controversy on the wood pulp processes is likely to accumulate a considerable technical literature of its own. The *Papier Zeitung* has just reproduced in a free translation an article on the subject from a French paper-maker's point of view, which appeared in the *Moniteur de la Papeterie Française* of the 1st April, written under the technical authority of M. E. Bourdilliat, and entitled "Etude comparative sur les pâtes aux bisulfites." This article, which contains much that is instructive, may be interesting to our readers.

M. Bourdilliat tells us that sulphite pulp will very soon make a revolution in the manufacture of paper-making materials, and will, it is to be hoped, lead us out of a dilemma into which we have fallen through foreign competition. He says:—

The patents on sulphite experience since 1866 are sufficiently well known, and there is no difference from first to last between them; it is superfluous to discuss their value. On the other hand, it may be interesting to show the different stages of this new industry, to prove its advantages and disadvantages, in fact, to show everything which earnest study of the question has taught us; and it is important to know the different methods and improvements which have been made in this chemical operation, and which by our experience we have found to be effective.

PREPARATION OF THE SULPHITE.

The bi-sulphite compounds may be regarded in the light of sulphurous acid combinations in solution, and are collectively more or less soluble. We will examine the bi-sulphite compounds which have as yet been brought before our notice, viz., those of lime, magnesia, and soda.

Sulphurous acid, which is the most important of our new lays, can be produced in several ways. By burning sulphur in contact with air; also from iron pyrites, and from the calcination of the mixture of sulphate of iron with lime and saw-dust, which has been used for purifying gas, containing about 40 per cent of sulphur.

The purest sulphurous acid is obtained by burning sulphur; that made from pyrites contains sulphuric acid and arsenic. The purest pyrites contains from 45 to 49 per cent of sulphur, of which from 40 to 44 per cent can be converted into sulphurous acid. In crude sulphur there is 95 per cent of sulphur: so 200 kilogrammes of pyrites is equal to 100 kilogrammes of crude sulphur. Sulphurous acid drives off carbonic acid from all its combinations, therefore can combine with the carbonates of lime, magnesia, or soda, as well as with the respective bases.

Bi-sulphite of lime can be produced in large quantities by introducing sulphurous acid gas (obtained by one or other of the before-mentioned methods) into the bottom of towers 20 to 30 metres high, in which limestone as it comes from the quarry is piled up; water

is allowed to trickle down from the top of the tower in a number of small streams which is then conveyed into receivers. The sulphurous acid must drive off the carbonic acid from the lime before it can combine with the latter, and the towers are built high on purpose to give sufficient time for this operation to take place.

If ordinary lime, i.e., burnt lime, could be used the combination would take place much more rapidly, and a height of 8 to 9 metres would then be sufficient; the water, however, falling on it would slake it and increase its volume, and the consequence would be that the tower would get blocked up, when the acid would only pass through with difficulty, or not at all. The same difficulty, only in a worse form, would take place with chalk.

As sulphurous acid is necessarily impure through containing sulphuric acid, it results that some sulphate of lime is formed, which is very difficult to dissolve, and, therefore, covers the limestone, so that it impedes the sulphurous acid acting upon it. To get rid of this sulphate of lime it is necessary to wash the limestone from time to time, and in order at any time to start working a fresh tower, several are built together with channels connecting them through which the sulphurous acid can be introduced into any one of them at pleasure.

The towers are built of brick or wood and lined out with 3 m.m. thickness of sheet lead, the joints of which must be united by burning. In addition to the heavy cost of the towers there are drawbacks to contend with, viz., irregular piling up of the limestone occurs in the tower, as it has to be introduced at the top, and thereby the passage of the sulphurous acid is impeded. In order to preserve the lead lining and to avoid repairs it is advisable to wall over the inside of the towers with silicious bricks, similar to the "Glover" towers for concentrating sulphuric acid.

Bisulphite of lime could also be produced without towers by means of an apparatus conveying the sulphurous acid gas into a chamber filled with milk of lime.

Bi-sulphite of magnesia is produced in the same way as bi-sulphite of lime, only with the difference that the magnesia is first calcined, and the towers can, therefore, be used of a height of from five to six metres: as the carbonic acid has been driven off by the burning of the magnesite, the magnesia is in a proper condition to combine very quickly with the sulphurous acid, and as sulphate of magnesia is much more soluble than sulphate of lime it is much better washed by the falling water.

Bi-sulphite of soda can be produced direct by substituting a solution of soda for the water in the tower, which is packed with some neutral material such as coke or bricks. Simple as this operation is, it is not to be recommended; it is actually cheaper to produce bi-sulphite of lime and to decompose this with sulphite of soda. From this is obtained soluble bi-sulphite of soda, which is used, and insoluble sulphate of lime results, which still containing some sulphite of lime can be used as antichlor or for filling up. The advantage in this last process consists in sulphate of soda costing only six to seven francs per 100 kilos., but soda costs twenty-one to twenty-three francs.

USE OF BI-SULPHITE.

The properties of sulphurous acid can be read up in any book on chemistry. It is sufficient for us to know that its solutions have an energetic effect on extractive matter, and that it affects the colour of materials by abstracting acids from them or makes colourless combinations with them, in which case one can detect the presence of sulphur. Sulphurous acid works as a reducer or acid extractor, whilst soda on the contrary dissolves the resinous matter attacking the fibre by oxidation, so that it is evident that we cannot use sulphurous acid by itself, but only in combination with a base, and for the following reasons:—

1. For a chemical to act properly on a material like wood, the latter should be sufficiently soft and spongy for the chemical to thoroughly penetrate it. In order to effect this the wood is boiled in contact with the ley at a high temperature. Now the solutions of sulphurous acid are very unstable, not only in contact with the air, but particularly affected by a high temperature, and cannot therefore be kept in store for any length of time: the sulphurous acid in solution would be converted in large quantities into gas, and the wood would be only in water, while the gas would collect in the upper portion of the boiler; in addition to this sulphurous acid at 60 deg. C. is a vapour.

2. Sulphurous acid does not attack gums and resins so strongly or vigorously that they can be washed out afterwards.

3. We know by experience that sulphurous acid by itself, even if it sufficiently decomposes the wood, gives it a reddish colour, especially if it has combined with it in a gaseous form or with steam. In presence of a base it is possible to prepare the ley beforehand, which moderates the volatility of the sulphurous acid at a higher temperature and hinders the formation of sulphuric acid, and also the colouring of the material under treatment.

According to the present established theory, which really has to do with the deoxidation which chemists ascribe to sulphurous acid, there is produced during the boiling large quantities of sulphuric acid, which more or less interferes with the energetic action of the bisulphite bases. We do not believe in this reaction, and therefore agree with Lioud that if sulphuric acid, and also necessarily sulphates of lime, magnesia, or soda are formed, so these combinations would be found in the ley, especially if they are as soluble as the soda salts.

The analysis of M. Joseph de Montgolfier, Assistant in Chemistry at the College of France, gave the following results as regards the ley:—

1. That there is not the slightest trace of sulphuric acid combinations, therefore, that no sulphuric acid is formed.
2. That the fresh unused ley of bisulphite of soda contains 126 grammes of sulphurous acid per litre, whereas after boiling there remains still 106 grammes. The difference explains the loss, to a

certain extent, which results from boiling; and, on the other hand, that a certain quantity of the sulphurous acid remains in combination with the therapeutics and resinous matter in the wood, or in the state of reduced sulphur: when the boiling is effected by direct firing (without steam), there is a greater loss. To prove this analysis, sulphite pulp, which had been prepared with bisulphite of lime, was burnt, and only contained 1.6 per cent of ash, so could not have contained any mineral matter.

The theory of the presence of sulphuric acid is, no doubt, incorrect, as in the spent ley almost all the sulphurous acid is recovered; there must, therefore, be some other explanation of the chemical effect produced.

We must here, however, mention that the ley had been used to boil 25 kilos of wood, and that it was produced from nearly pure sulphurous acid. In manufacturing sulphurous acid on a large scale from pyrites, sulphuric acid is always formed, consequently with the produced bisulphite, combinations of sulphate of lime, magnesia, and soda will also be produced. In such a case an analysis of the spent ley would show the presence of these combinations: with sulphuric acid, and a test would prove whether the ley contained any before being used.

We are not credulous enough to believe that we have arrived at the true theory in the process of boiling, for very careful investigations, which are beyond us, would be required to prove this. We only give our views on the subject that sulphurous acid separates the extractive matter of wood under the influence of heat, and bleaches the colour in the material, whilst uncombined sulphur is driven off, and that finally the resin, which is hardly attacked by the sulphurous acid, forms soapy compounds, more or less soluble, with the bases of the bisulphites. It is even possible that the sulphur and the soaps may form gummy combinations which adhere to the fibre, increasing its weight.

According to these foregoing remarks, especially to the circumstance that no sulphuric acid is produced in the boiling, it would seem that it would suffice to use a boiler made of such metal as would withstand the bisulphite combinations, and by the use of such a metal dispense with the lead lining. We merely mention this improvement in passing, as every experienced man will know that not only the construction of the boiler would be facilitated, but also the cost of repairs reduced, the boiler would last longer, and a great many difficulties which now appear to be in the way would be removed. The metal that would perhaps be best suited would be a sort of copper, which M. Lioud not long ago patented. Experiments which are now in progress will put us in the position of judging whether this metal is fit for the purpose.

All manufacturers were astonished, at the immense yield obtained by the sulphite process, as it was much larger than that derived from the soda process, and even much greater than most cellulose, which, according to chemical analysis, is contained in wood. This additional weight, however, is not obtained by the addition of mineral (lead), which may be determined by analysis, but is owing to the sulphur and resinous combinations which burn off without leaving any residue.

COMPARISON BETWEEN THE DIFFERENTLY WORKED BISULPHITE PULPS—BOILING, &c., &c.

We will now explain the respective systems by which the sulphite pulp is produced, viz., by bisulphite of lime, magnesia, and soda. The sulphite of lime pulp, as it comes out of the boiler, is hardly fit for better-class papers than news and ordinary printing; if it is required for better sorts it would be necessary to thoroughly wash it, and then bleach it, by which it would lose according to M. Knödel (No. 47 of the *Papier Zeitung*), 28 per cent. We had the opportunity of mentioning this to one of the most important Swiss paper-manufacturers, and he confirmed that the loss was considerable in washing and bleaching.

We recommend manufacturers not to work large quantities of sulphite pulp without having washed it beforehand one or two hours, as it contains sulphurous acid, which attacks the metal of the engines, as the above-mentioned manufacturer has found out by experience. The washing may be accelerated, and the sulphurous acid driven off, by adding muriatic acid. The loss which takes place in the washing is not fibre, but the combinations of sulphur, resin, and lime, which are set free through the action of the roll, and it is this which is lost, being washed away by the drum-washer.

The boiling process seems to be simple enough, and one has only constantly to renew the inner lining of lead, which suffers more from the expansion and contraction of the boiler plate than from the action of the bisulphite or gases which are generated during the process of working. Great importance seems to be attached to the size of the boilers, as they are built 4 metres in diameter and 30 metres long. We cannot understand, however, how the size of the boiler affects the boiling when the trials made in an experimental boiler containing 25 kilogrammes of wood did not vary in result from those done in a manufacturing boiler holding 1,500 kilogrammes.

We will not dispute about the cost of production of sulphite of lime pulp as we have not got the figures concerning keeping the boiler in repair and duration of same, which really constitute a considerable portion of the cost. Moreover, no one in France has yet been able to estimate the cost of production.

Sulphite pulp made by the magnesia process appears to be better suited for ordinary and finer paper as it is cleaner, and contains less heavy matter; it washes well, and the best rags do not bleach better. We do not know whether this result is owing to more careful treatment of the wood, or whether it is owing to the use of magnesia instead of lime, but will merely state the facts which may explain the results.

The boiler is jacketed, and is heated by blind steam, so that the ley inside does not become weaker (more dilute.) Moreover,

as the ley is used in a more concentrated form than in the lime process, and the combination of sulphurous acid with magnesia is less stable than with lime, so the chemical effects must be greater in the same time and with the same temperature. We may assume that indirect heating from without is indispensable.

During the process of boiling, the pressure in the boiler and in the steam jacket varies a good deal. In the boiler the temperature is more elevated, which goes to prove that sulphurous acid in the gaseous form is given off, which, as before explained, takes a higher tension than steam at the same temperature. During the boiling, care must be taken to let off constantly the superfluous gas, so that the pressure in the boiler and the steam jacket does not vary more than two atmospheres. If these precautions are not taken, an over-pressure might readily cause an explosion. The method of boiling with bisulphite of magnesia with indirect heat is well founded. It will be noticed that sulphite pulp produced by this system contains charred portions, which goes to prove that some of the wood which has not been covered by the ley has been in contact with gaseous sulphurous acid. To counteract this, it is not sufficient to cover the wood in the boiler with a perforated plate of lead in order to keep it under liquor, as in consequence of the constant evaporation of the liquor the time must come towards the end of the boiling when the wood is not entirely covered, and as the boiler is stationary so necessarily this part of the wood which will be uncovered is acted upon by the gas, and becomes charred. One will now comprehend that the boiling with bisulphite of magnesia must be very carefully watched to regulate the pressure and keep it even. It is necessary to have two men constantly in attendance, as it would be dangerous to trust to one man on account of the abundant amount of gas given off, and the consequent smell. It is not difficult to detect imperfections in the lead lining in the boilers during both processes.

Magnesia pulp is more expensive to produce than lime pulp; less on account of calcined magnesia being more expensive than lime as on account of the loss through washing and bleaching—this may be the case, but we are not fully informed thereon. It may be assumed that sulphurous acid is given off in both processes in the same way.

The additional price of 7 to 8 francs per 100 kilos of the magnesia over the lime pulp, may to a great extent be due to its being of a better quality.

Soda Sulphite Pulp.—We have already explained above how bisulphite of soda is produced, but have no practical experience in the matter which would be of any value, as the equivalent value of the pulp. The first manufactory which will be worked on this system is now being built, and we shall be able to learn the result; we have concluded that the ley has a similar effect to that of the magnesia, and that it is in any case better than that of the lime.

At first direct steam is employed for the boiling, and afterwards boiling is effected through a serpentine pipe (Patent Kudelaki). For boiling a revolving boiler is used; by this the charring of the fibre is avoided, and the process accelerated. The whole arrangements of this process appear to deserve the attention of manufacturers, but we will reserve our opinion upon it until it proves itself to be practical.

We will conclude by putting together a few facts which appear to us correct:—

- 1.—Lime sulphite pulp will be used for new and common printing papers, or to all sorts of paper which will not necessitate the washing and bleaching of the pulp.
- 2.—Magnesia and sulphite of soda pulps will, on account of their cost of production, be used only for better and finer sorts of paper.
- 3.—It appears clear that copper, bronze, or some other metal, which will resist the action of the sulphurous acid, must take the place of the steel-plated boilers lined with lead.
- 4.—That the towers, which, on account of being 90 feet high, cost at least 90,000 francs, will be superseded by a less costly arrangement.
- 5.—For cleaning the boiled pulp, similar strainers to those used for removing the knots and unboiled portions of straw will be used, by which means the pulp would be cleaner and freer from shavings.

THE "GERM THEORY" OF SILKWORM DISEASE.

IN 1865 the weight of the silk-cocoons produced in France was 8,000,000 lb. Large as this amount seems, we may be able to discover the enormous falling off which the 1865 crop exhibited, when we learn that in 1853 the weight of silk produced was 52,000,000 lb. In a single year—that of 1845—the fall produced a loss of 100 millions of francs. In 1853 the revenue was 130 millions of francs; and we also learn that in the twenty years prior to 1853 the revenue from silk culture had doubled itself. The vast and overwhelming nature of the catastrophe, which thus threatened the commercial prosperity of France, can be fairly judged from the foregoing figures. During a period of fifteen years the silkworms (or caterpillars of the silk-moth), had died off by thousands, smitten by a disease which appeared mysterious alike in its origin and in its spread. No such calamity can befall any nation without attempts being made to stay the progress of the disease. As in the case of the existent vine-disease, remedies were proposed by the score. One author, writing in 1860, remarks that the *materia medica* of the silkworm "is now as complex as that of man. Gases, liquids, and solids have been laid under contribution. From chlorine to sulphurous acid, from nitric

said to run, from sugar to sulphate of quinine—all have been invoked on behalf of this unhappy insect."

To such a pass had matters come in 1863, that the Minister of Agriculture, as representing the French Government, signed an agreement, binding himself to pay 500,000 francs to the happy discoverer of a remedy which was said to be successful in arresting the disease. The remedy was tried, but without success. It was at this juncture, in June 1865, that Pasteur appeared, prepared to undertake a thorough and scientific investigation into the mysterious plague which, so far, had ravaged the insect tribe unchecked and at will.

Prior to the appearance of the dread disorder—which, by the way, was known as *pebrine*—it was noted that an affection named *muscardine* had attacked the silkworms. One Basal had shown that the "*muscardine*" was undoubtedly caused by the growth within the silkworms, of a minute parasitic plant. In due time, these disease-plants gave origin to their microscopic "spores," or seeds. The spores, conveyed by the wind, carried the disease to regions in which it had been unknown. "*Pebrine*," however, was a far more fatal malady than "*muscardine*." The former caused black spots to appear on the bodies of the worms, and from this fact the name of the affection was derived. It affects the growth and nutrition of the little spinners of the silken thread, and finally causes their death. Doubtless the prior discovery of the parasitic and plant-nature of "*muscardine*" assisted Pasteur somewhat in his search after the cause of the "*pebrine*"; and he was armed likewise with other items regarding the nature of this plague, which proved useful in guiding his footsteps towards its true seat and origin. So early as 1849, curious rounded bodies, showing apparently independent movements, were known to occur in the blood of the silkworms. These "*corpuscles*" multiplied in the insect's body, and, undoubtedly, as was proved by Cornalia, caused the disease of the insect. Later on, these mysterious "*corpuscles*" were seen to inhabit even the eggs laid by the silkworms, and from which new silkworms spring. The egg was thus apparently infected from the parent, and in turn, the infection, of course, grew with the silkworm, and thus became a hereditary complaint, propagated from parent to offspring.

A silkworm suffering from disease of this nature, seems to be affected in every part of its frame. The "*corpuscles*" literally reign over its body. When the diseased insect begins to "*spin*" its attempts are in vain, for the silk glands, instead of providing the fluid material, as in health, are filled with the corpuscles. Complete disorganisation of the structure and life functions of the unhappy insect prevails, and it ultimately dies, vanquished by the hidden enemies that have thus multiplied in its blood.

Pasteur, at the outset of his discoveries, drew attention to one very important point. The corpuscles, he saw, were small, and comparatively undeveloped in the egg. In the young worm even they might escape notice. But with the insect's growth its "*un-bidden guests*" also increase in number and size; while, lastly, in the chrysalis, and in the full-grown moth itself, the corpuscles are large and readily seen. Hence appeared clearly enough the reason why the old methods of testing the eggs was fallacious and untrustworthy. The egg might apparently be healthy, and yet contain the germs of the disease fully represented in its constitution. But it is different with the moth. By passing the egg, the disease was liable also to be overlooked. By beginning with the diseased parents, or moth, in which the presence of the corpuscles could be fully traced, no difficulty was experienced in pronouncing an opinion regarding the probability of the disease being reproduced.

Like all reformers Pasteur experienced great difficulty in persuading the silk-growers to accept his dicta. They ignored the fact that a fine-looking cocoon might harbour a diseased moth. The egg, as we have seen, gave no hint or prophecy of what the moth might become; and as often as not, the diseased eggs, chosen by the growers, produced bad moths. So convinced was Pasteur of the surety which lay in taking the moth as the fulcrum upon which to move the lever of thought and research, that in 1866 after inspecting fourteen parcels of eggs which had been selected for hatching, he wrote and deposited in a sealed packet his view of the probable results which would follow the development of the eggs. In 1867, the growers told their story. Pasteur's letter was then opened, and his prediction was so far verified that in twelve out of fourteen cases the results agreed exactly with his views. He had said in his letter that many of the worms would perish completely, whilst others had well-nigh been extinguished by the disease, and the result was as he had predicted. Had the moths of 1866, from which the eggs had been taken, been inspected, as Pasteur advised, none of the fourteen packets of eggs would have been allowed to undergo development. Two packets of eggs he pronounced in 1866 to be sound, and born of healthy moths. These packets bore healthy caterpillars and thus in a reverse way verified the correctness of his views.

The result of Pasteur's labours in connection with *pebrine* may be predicted from the foregoing account. By rearing healthy eggs, and by the destruction of all unhealthy and diseased moths and worms, Pasteur restored to France the well-nigh ruined industry of the silk-growers. He elaborated his methods to such an extent and perfection, that he was enabled almost to predict the exact extent to which the disease would prevail in a given case. He showed that infection was conveyed by the wounds which the worms inflicted on one another with their claws. He proved the infectious nature of the disease by infecting a mulberry leaf with the diseased matter, and by showing that the healthy worms which had fed but once thereon, in due time became diseased. He demonstrated that only by destruction and isolation of affected worms could the disease be stamped out, and a new and healthy breed secured. In a word Pasteur showed that *pebrine* was due to a plant-growth and propagation within the animal frame.—*Health.*

CINCHONA.

CINCHONA CALISAYA

At the meeting of the Linnæan Society, on Thursday, the 3rd ultimo, a valuable and interesting paper was read by Mr. J. Elliot Howard, F.L.S., the well known quinologist upon *Cinchona* "*Calisaya*, var. *Ledgeriana*, How., and *C. Ledgeriana*, Moens," and in illustration of his remarks there was a magnificent display of *Cinchona* plants, bark, seeds, dried specimens, &c., brought together by Mr. J. Elliot Howard himself and by Mr. Thomas Christy, F.L.S., and the keenest interest was taken in these by the members of the society present.

Mr. Howard commenced his paper by recalling the fact that in 1866 he had, in a paper before the Botanical Congress, quoted Mr. Markham's statement that although the *Cinchona Calisaya* not only was the most famous of all the S. American bark trees, and in its native forests the most beautiful in appearance and the richest in quinine, it had not proved a success in India. Mr. Markham deplored the stunted, shrubby appearance of the trees growing in India three or four years old, with a height of less than 6 feet, and 6 inches girth; "as different as possible," he said, "from the glorious *Calisaya* of the Carabaya."

At the time Mr. Howard ventured to express a hope that, nevertheless, the time would come when *Calisaya* must, in India, assume its rightful position as the queen of all quinine-growing species, and this hope, he said, had been now realized by the introduction of mixed seeds of the very best kinds of *Calisaya* by Mr. Ledger, a service very ill requited by the Dutch Government.

In the *Journal of Botany*, of November, 1881, Dr. Trimen published an account of a *cinchona* which he called *Calisaya Ledgeriana*, Moens, being a tree that had been found growing on estates in Ceylon, five or six years old, the character of which was not known until Mr. Moens's visit to the island in 1880, when he pointed them out as *Ledgerianas*, and Dr. Trimen thereupon gave them the name of *C. Ledgeriana*, Moens, but, as Mr. Howard showed, they realised the description given by Markham of the Indian *Calisaya* as stunted and shrubby, and prematurely decayed.

There was nothing, however, to show that these trees had been raised from seeds brought by Mr. Ledger, and in fact their identification rested upon the botanical accuracy of Mr. Moens's description.

Mr. Howard seemed inclined to believe that the plant figured and described by Dr. Trimen is the male form of *Cinchona Micrantha*, var. *Calisayoides*, the female plant of which is figured in Curtis's "*Botanical Magazine*" as *C. Calisaya*, var. *Josephiana*, by Sir J. D. Hooker. It also bears some resemblance to the plant described by Howard as *C. Forbesiana*.

Mr. Howard was emphatic in his opinion that this *Micrantha* variety ought to be avoided in cultivation, and he mentioned that he was more free to indicate the mistake committed by others, because he himself had been deceived into growing and distributing as "*true Ledgerians*" seeds forwarded to him as such by Mr. Moens as *Ledgeriana*, but which turned out to be nothing of the sort, as was fully proved when he cut down one of the trees and analysed the bark, comparing it also with bark sent to him from Jamaica grown from the same seed. He had been misled by the name *Ledgeriana* attached to the E.I. seed which he raised, and was now sensible that the "*Micrantha* like aspect" of the trees noticed by his Indian friends more correctly indicated their true character.

It was evident, Mr. Howard continued, that none of the low varieties of *Calisaya* would repay cultivation, and that no reliance can be placed on any description unaccompanied by careful observation.

He called attention to some plants on the table, grown from seeds from the Yarrow estate, Ceylon, as taken from trees that yielded 7 to 12 per cent. of quinine, and he pointed out the rich velvety appearance of the leaves that is so highly characteristic of the glorious *Calisaya* of the American forests.

With the exception of Mr. Ledger, no one had received from South America true *Calisaya* seeds except Mr. T. Christy, who had contributed a valuable collection of specimens grown from this seed. Mr. Howard explained how he had planted seeds given to him by Mr. Christy, at the same time with those received from Ceylon, and they grew up side by side, evidently coming from the same stock; but Mr. Christy's seed was rather the more vigorous

and showed distinctly the two varieties of *Callisaya Verde* and *C. Morada*.

When Mr. Ledger's seeds were in this country, he (Mr. Howard) was consulted by Mr. Moens regarding them, and gave a favourable judgment from the appearance of the capsules, as being of the *Microrcarpa* variety of *Callisaya*.

Dr. Weddell's *Microrcarpa* differs, however, from *Ledgeriana* in the character of the under surface on the leaves, but Dr. Weddell gave him specimens of *Callisaya barks* obtained in his second journey, which closely resembled the *Verde* and *Morada* of Mr. Christy.

Nothing can be more important for the classification of *Cinchona* than a close examination of the barks (said Mr. Howard), and he handed round branches of both *C. Callisaya* var. of *Ledgeriana* How., and of the *C. Ledgeriana*, Moens, to show the difference between them, which was, in fact, very marked.

He then went on to quote from Mr. Van Gorkom's recent book to the effect that in Java the *Ledgeriana* were easily recognised by the peculiar uniformity of their bark and the small white flowers, and he said that in that island great care was taken to preserve the best trees, whereas in India he was afraid many of the best trees of *Succirubra Officinalis* had already been cut down.

Mr. Howard then went into the question of hybridisation, and remarked that there had been more imagination than fact introduced into this controversy. He lamented the great loss to science in the early death of Mr. Molvor, who had gone into the matter critically. He had received from him carefully selected specimens of hybrids, but they did not suffice in his opinion to establish any theory. He would not deny hybridisation, but he thought it was very local, and quoted letters from Mr. Ledger to the effect that whilst trees on the outer fringe of the plantations deteriorated, those in the inside continued to give the best quality of bark, and though differences still appeared in their foliage at the time of flowering, they were visited by thousands of humming-birds and bees.

He stated that the wrong species had been cultivated in India and Ceylon, the *Succirubra* having there taken the place of the superior *Callisaya*, the *Succirubra* being inferior for both pharmaceutical and manufacturing purposes.

Mr. Howard exhibited a bark which had been sent to him by Mr. Molvor that had been taken from a tree raised from seed sent out to India, and in which owing to cultivation, the produce of quinine had increased in about fourfold ratio. In Mr. Howard's opinion it is not unlikely the same result may occur with *Ledgeriana*.

Mr. T. Christy said "that specimens of *Cinchona* had been sent to him from Bolivia by a botanist who had been in his employ here for some time, and for whom he had obtained an appointment with a gentleman leaving for La Paz, the owner of large plantations. Mr. Christy impressed upon him, before he went out, the extreme importance of gathering the flowers, leaves, and the seed pods of all the varieties of *Cinchona* cultivated on the plantations, and that gave the best results, and he had very fairly followed out these wishes. Mr. Christy then drew attention to the dried specimens of the various varieties which were placed before the meeting, and acknowledged the great assistance he has received from Mr. Howard in classifying these plants, and he said the result was, that after a great many letters passing, and a great amount of information being thus diffused, that planters in Bolivia had found that it was to their advantage to grow the *Callisaya verde*, a very large tree, and which they found answered their purpose the best of any. It did not yield quite as much quinine as the *C. Morada*, but the growth was much more rapid and the yield of the bark was very much greater. Taking into account the twenty-days' mule journey which this extra quantity bark had to support, it still paid better to cultivate than the richer variety of *Callisaya morada*, on account of the larger yield. To show the value of such a Society as the Linnæan, and of being able to compare living specimens," Mr. Christy continued, "since coming into the room, one of the plants here had been recognised by Mr. Howard and Mr. E. M. Holmes as identical with the specimens of bark sent home and named *Rubraenada*." Mr. Howard had informed him that the plant was raised from the seed he (Mr. Christy) had sent him. He had been able to identify this plant of *Callisaya Rubraenada* with the dried specimens by the appearance of its foliage and marking.

Another fact wanted ventilating, and that was that they had tried in every way to explain to friends in Bolivia, who are on the plantations, that what was particularly wanted was the *Callisaya* known here under the name of *Ledgeriana*. It was explained

thoroughly that what was wanted was the variety with the red stems and red leaves called *Reja* by the natives. They replied, seed specially marked had been sent home several times, and different journeys were made to the mountains for specimens, but that they really could not find trees with this peculiar red marking.

Mr. Howard, when reading his paper, remarked that he noticed that the leaves turned red at a certain time of year.

Mr. Christy remarked it was curious that only that morning he had taken from a *Callisaya* plant in his hot-house a bright red leaf, which he thought was dead or diseased. If he had brought it, it would have been seen at once that it was of a brighter crimson than on any other plant produced. There was no doubt that the leaves did change colour at certain times of the year.

They seemed to notice out in Bolivia that the *Callisaya Morada* seed was thinner and more pointed than the *C. Verde*.

On looking at the dried specimens Mr. Howard remarked to Mr. Christy that a change was fast taking place in the distinctive marks and shape of the leaf; some leaves were getting quite pointed, like *C. Morada*, and in the Bolivia dried specimens, they called them lanceolate shaped, &c., &c.

Mr. Christy said he had brought with him the *Callisaya Ledgeriana* obtained from seed sent from Java, and it agreed pretty nearly with the plants brought there that evening, &c., those of the *Callisaya verde*. Mr. Howard's conclusions were, it seemed to him, that the true *Ledgeriana* giving 7 to 12 per cent of quinine agreed exactly with the plants raised from Bolivian seed. Again, the cinchona planters agree with Mr. Howard in stating that the only varieties worth growing is the *Callisaya*, and they select the *Callisaya verde* as giving them the best return for their capital expended.

Mr. E. M. Holmes asked if Mr. Howard had seen Dr. Trimen's recent paper in the *Journal of Botany* for May 1888, in which Dr. Trimen stated that there are no *Ledgeriana* in the East which have not descended from Ledger seed. If he understood Mr. Howard rightly there were several forms passing under the name of *C. Ledgeriana* which were not the true plant, but that some of the plants raised from Mr. Christy's seed were identical with the true *Ledgeriana*, and that these were distinguished by the velvety gloss and the ciliated margin of the leaves. He could now understand how it was that the Bolivian planters did not recognise the *reja* variety because it was obvious that the colour was only temporary. Mr. Christy's seed, judging from the plants exhibited, evidently includes not only the true *Ledgeriana* but also the *Morada* and several forms of the *Verde*, such as the *Rubraenada* and *Alborenada*.

Mr. Howard replied that he had not seen the article alluded to.

Mr. Howard made a few remarks in reply, but as we were unable to decipher, satisfactorily, the notes of those made by us at the meeting, we ventured to ask Mr. Howard to transcribe them himself, and he has very kindly favored us with the following:—

My review of the whole subject is briefly as follows:—Dr. Trimen and Mr. Moens, wishing to describe (as a new species) the very same *Ledgeriana* trees, of which I had given description and analyses of the bark, with plates drawn and colored by our most able artist, and which I had thus published as a variety of *Cinchona Callisaya*, took for typical specimen of the same a tree found in Ceylon, derived apparently from seed given by Mr. Molvor, of uncertain origin. I think it will be evident to any botanist comparing the plates and description, that they differ very widely, and on Mr. Moens' own authority I claim that mine alone are authentic. I believe the tree figured as *C. Ledgeriana*, Moens, to be no *Callisaya* at all, but either a true species standing intermediate between *Callisaya* and *Miconia*, or a mere variety of *Miconia*. Comparison of plants manifest this still more closely, and also shows the very close resemblance between the *Ledgeriana* and the *Morada* and *Verde* varieties of *Callisaya*, all perhaps standing under the var. *Microrcarpa* of Weddell. The real *Ledgeriana* is not the *Verde*, nor the *Morada*, but that which is known in its native habitat as the *reja* or red, from the leaves turning a bright red (under circumstances), as noticed by Mr. Ledger in Bolivia, and by Mr. Christy and myself in our authentic plants. The leaves of these seem to me more sensitive both to the influence of light and temperature than the others named. The *reja* seems to be a more delicate tree than the *Verde*, and is (perhaps consequently) not found in patches, but isolated; neither has it as yet been cultivated. I have noticed various points of difference from the *Pseudo-Ledgeriana* of Trimen which would no doubt in part disappear,

through the rough influence of climate and weather; but the glorious Calisaya of the Bolivian forest cannot permanently be confounded with the *micranthoid* variety with which it has been supposed identical. The bark alone, as noticed by Mr. Von Gorkom, is a sufficient distinction.—*Ceylon Observer*.

CINCHONA CULTIVATION: ITS FINANCIAL ASPECTS.

A PLANTER, S. E. Wynaad, writes:—There has, within the last three years, been quite a rage for cinchona planting. Every one has taken to planting cinchonas, to a great or less extent; and we all have, or have had hopes of making fortunes out of the bark, and being able, notwithstanding the fickleness of our old love of coffee, to retire, some of us, after many years of exile, to England, and those home comforts which memory palates for us in the brightest hues.

The cinchona mania has some *raison d'être*. Money has undoubtedly been made, and is now being made, from cinchona; and estimates, drawn up by authorities on the subject, show us what handsome profits are still likely in their opinion to be derived from the cultivation. But, looking at the rapid extension which has been made in cinchona cultivation of late, the question naturally arises, will the demand for, and consumption of, the bark keep up with the supply, so as to insure paying prices some years hence, when trees now being planted will have reached the producing stage? Philanthropists may rejoice when "the bitter blessing" is brought within reach of the poorest in the land; it will be well for the world generally; but will it be altogether satisfactory for the individual planter? Though he has his fair share of the milk (unadulterated) of human kindness; it was not philanthropy alone which induced the planter to spend his best years in fostering the fever-slayer; *ceteris rebus sans dire*. Neither was it revenge on the malignant goddess, Malaria, for a shattered constitution.

I calculate that there are now growing in Pykara, Neddiwattum, Oucherlony Valley, and S. E. Wynaad, 5,000,000 cinchona plants; 10,000,000 may be put down for North and South Wynaad, Ootacamund, Coonoor, Kotageri, Kartary, Koodahs, &c., giving a total of 15,000,000 plants for the Wynaad and Nilgiris. We have besides Mysore, Coorg, Travancore, and other districts in Southern India, and Sikkim and Darjeeling in the North, where cinchonas have been extensively planted; and I do not think I would be far wrong in putting down another 15,000,000 as the number of plants now growing in these parts; giving, with the cultivation in Wynaad and Nilgiris, a total of 30,000,000 plants for the whole of British India. During the next two planting seasons, 1883 and 1884, I believe a larger number of cinchonas will be planted out than in any previous years; and by the year 1890, there will be in British India not less than 40,000,000 cinchona trees (yellow, crown, and red barks) none of them less than 5 years old, with an annual producing power, allowing ½ lb per tree, of 10,000,000 lb of bark, that is to say, more than half the amount of the present average annual outturn of bark in South America, from all sources. Then, there are Ceylon, Java, Jamaica, Mexico, and other countries which have gone, and are still going, in largely for this cultivation; and though it has been reported that the South American cinchona forests, owing to the wholesale harvesting, are rapidly decreasing, it is difficult to get reliable information on the subject, and it seems unlikely that South America will cease to be a large producer of bark for several years to come. I do not think it would be too much to put down the production of bark, in 1890, in countries other than British India, at 40,000,000 lb, which would bring the whole world's production to the grand total of 50,000,000 lb annually; or, as far as I have means of learning, more than double the present annual consumption, and, even allowing for a large yearly increase in the demand for bark, far more than is likely to be required to supply the world's wants at that date.

At the present time, inferior bark (twig and branch) is not worth shipping; being "a drug" in the market the druggists will have none of it; and if the German brewers want to make use of it instead of hops for their beer, one would naturally suppose that they would be willing to give for it what would at least pay the grower for the freight and charges, especially this year when the supply of hops was reported to be short. It remains to be seen whether the price of a great deal of our stem bark will not, within the next few years, fall to a point at which it will barely pay us to grow it. There is scope for the extension of the consumption of quinine of course, but it is not unlimited scope. Those countries favoured with cheap labour, and suitable soil and climate, may be able to derive fair profits from cinchonas for some years to come; and

amongst cinchona growers, he who is most careful in the selection of his seed, and gets a strong-growing variety with rich bark to flourish on his land, will be better off than others. But to those who may contemplate going in for cinchona cultivation, I would point out that the grand results talked of as having been obtained and being now obtained by some in this branch of agriculture may, as far as they are concerned, be relegated to the limbo of past possibilities.

THE GARDEN.

CINERARIAS BY CUTTINGS OR OFFSETS.

THE cineraria, as is well known, is so apt to vary when raised from seed, that no two plants in a thousand can be relied upon to turn out to be exactly alike. Yet one often meets with a sort among a batch of seedlings that it would be desirable to perpetuate. But as this cannot be done by means of seed sowing, the grower must adopt the only known method of propagating the characteristics of any particular sort of this or any other kind of plant which has the same peculiarity of varying from seed; that is, by means of cuttings or offsets. The difference between a cutting and an offset is that the former is a shoot or piece of growth without roots, while the latter is a shoot with roots more or less, and always to be found proceeding directly from the underground rootstock of plants of the same character of growth as the cineraria. True, cuttings are not often to be had from our present subject; but if rightly treated, the plants will throw large numbers of offsets. When it is intended to increase the number of any desirable variety in this way, let the stems be cut ever close to the ground when they have finished flowering. Water sparingly till they start into growth, and keep them in partial shade, in such a position as that they will not be exposed to the bright rays of the midday sun, but may have the sun morning and evening. The best place for them is a spot behind a wall facing north, not overhung by trees, but protected from the meridian heat and light only by the wall. They should not be placed here till all danger of frost is past, or if they are, means must be taken to protect them at night. They succeed best when planted out; indeed, they should not be kept in their pots, because they will not freely form the offshoots that are wanted except they have ample room to ramble and push their roots in. Never allow them to become dry, but see also that the drainage is such that they cannot possibly become stagnated with moisture. The compost must be light, rich, and open; the best that can be made is composed of light fibrous loam, old, well-rotted stable manure, and leaf mould, along with plenty of sand to add to the porosity of the mass. The offshoots may be taken off when they have attained such size as that they may be handled freely. They should be removed with a sharp knife, after clearing the soil away from them with a blunt-pointed stick. Pot them in the same character of compost as that already described for planting the parent plants in. Let the pots be small thumbs, and place them when potted in a close frame, which must be kept close and shaded for a week, after which they may be gradually inured to air and light, but the latter they should have only in the morning and afternoon till well on to autumn, when they will do without shade. After the plants are well rooted they may be potted into pots a size larger than those they were put in to strike root, and in every way afterwards they require the same treatment as seedling plants.

POLYANTHUSES.

These are very deservedly increasing in popularity. They are found to be among the most beautiful and free flowering of spring flowers. We are speaking of the fine strains of sorts that may now be obtained from seeds—not the high-class but more difficult to manage kinds, as florists' flowers. These latter are not of much use for mere decorative purposes, but the former are becoming indispensable to flower gardeners, and to all who wish to have a long period of beautiful floral display in their gardens. When they have finished flowering, all the flower stems should be cut away, except those which may be wished to bear seed. Only the very best sorts should be kept for the purpose of seed sowing; those with the most clearly defined colours, the largest and best formed flowers, and which also possess good substance, only are considered the best. Another point to be regarded as strongly desirable is the strength of the flower stems; if they are weak the flowers never show up to advantage, therefore it is desirable that the seed-bearing parent should have stout stems, capable of

bearing heavy heads of flowers erect. After they are done flowering, the plants should be moved to a somewhat shady position, where they will be exposed only to the morning and afternoon or evening sun. Strong sunlight scorches the plants and weakens them, and they die from sheer exhaustion when fully exposed to the sun's meridian rays. They may be divided before being planted in their new quarters, and should be well watered till they establish themselves.

MINERALOGY.

IRON ORES.

On the Iron Ores, and Subsidiary Materials for the Manufacture of Iron, in the North-Eastern part of the Jubbulpore District; by F. R. Mallett, F.G.S., Geological Survey of India.

From time immemorial the Jubbulpore district has held an important place amongst those centres where the smelting of iron has been carried on in the native method. Plentiful ores, extensive jungles for the supply of charcoal, and proximity to thickly populated alluvial tracts of country, combined to give Jubbulpore a commanding position in the old days before railways had brought the native hearths into an unequal struggle with the blast furnaces of England. Even now iron is made on what, from the native point of view, must be considered a large scale, numerous furnaces being scattered over the iron-bearing portions of the district.

The advantageous central position of Jubbulpore, now that it is in railway communication with the richest parts of the surrounding provinces, is too great to have escaped notice with reference to the manufacture of iron on European principles. As far as was known, ores and flux were to be had in abundance, and the means for distributing the manufactured iron to the surrounding markets was at hand. But the often-experienced difficulty of keeping large furnaces in blast with charcoal, and the absence of any available coal, were a deterrent to any decisive action.

Within the last year or two, however, the discovery of workable coal by Mr. T. W. H. Hughes, in the immediate neighbourhood of the Jubbulpore district, has given the question a new aspect. A line of railway from the new coal-field at Umeria to Murwara (Katni), on the East Indian line, has been proposed, and the preliminary surveys already executed.

The question of fuel, then, being in a fair way towards a satisfactory solution, it became important to ascertain whether the generally received opinion as to the abundance and excellence of the Jubbulpore ores was fully borne out by fact. I was consequently directed, in the early part of this year, to visit the more important places where iron was known to occur, with a view to forming an opinion as to the extent of the deposits, and the feasibility of working them, and to collect samples for subsequent analysis. The question of flux and other subsidiary materials was also to be looked into. The following paper, then, embodies the results of my work in the field and laboratory.

The iron ores, for purposes of description, may be regarded with reference either to their mineralogical characteristics, their geological distribution, or their topographical position. The accompanying map, the geological work on which is mainly, and indeed, with reference to the area with which we are more immediately concerned, exclusively, due to surveys executed by Mr. C. A. Hackett in 1869-72, shows the distribution of the different series of rocks. It will be seen that between the great spread of Vindhyan sandstones on the north and Deccan trap on the south, both of which formations are almost barren of any metallic wealth, there is a belt, some 30 miles wide, where a very varied and intricately disposed assemblage of rocks occurs. It is just here that the band of iron-bearing transition strata, which stretches eastwards for more than 200 miles through the Son Valley, comes in contrast with the thickly populated alluvial belt through which the Nerbudda flows westwards for about the same distance. Hence one of the most important advantages which the iron-smelters of Jubbulpore have enjoyed. Hematite ores similar to those of Jubbulpore are known to occur largely in the wild country to the east; but there are not the same facilities there for disposing of the manufactured product.

The formations just mentioned include—

Alluvium.
Rock laterite.
Deccan trap.
Lameta group.
Upper Gondwana.
Coal measures.
Tulshir group.
Upper Vindhyan.
Lower Vindhyan.
Bijawur or transition series.
Gneiss.

The Bijawur series and the rock laterite are those with which we are more immediately concerned now, for it is in them that nearly all the iron ore is contained. (1) By reference to the map, then, one sees at a glance the general lie of the iron-bearing tracts, which are those coloured respectively purple and burnt sienna, although it is only in certain portions of those areas that the ores are found. The Bijawur ores occur more especially in the Pergunnas Khumbhi and Gawalpore, while the Pergunna Bijeragorah contains the greater portion of the laterite ores.

(1) Some ore also occurs in the Gondwana beds, but it is "very impure and requires much selection and cleaning," and is "very barely worth working" (H. G. Medley, Memoirs, Geological Survey of India. V. II, p. 276.)

Mineralogically considered, the iron ores are almost exclusively varieties of hematite and limonite (or red and brown hematite), the former being especially characteristic of the Bijawur, and the latter of the newer formation. They may be classified thus—

| | | |
|---------------|-------------|---|
| BIJAWUR ORES | 1, Hematite | Schistose hematite. Micaceous iron. Jasper-hematite. (2) Semi-schistose hematite. Manganiferous hematite. |
| | 2, Limonite | Pisclitic limonite, breaking with smooth conchoidal fracture. Pisclitic limonite, breaking with rough uneven fracture. Ordinary laterite, some parts of which contains a high percentage of iron. |
| LATERITE ORES | 1, Limonite | |
| | 2, Hematite | |

Magnetite has been found in small crystals disseminated through the hematite beds of Sehora, but I am not aware of its occurring anywhere in such quantity as to entitle it to be included in the above list as an ore.

BIJAWUR ORES.

The Bijawur series has been subdivided by Mr. Hackett thus (in descending order):—

Chandardip group.
Lora
Bhitri
Majhauhi

It is in the inferior strata of the Lora group (so called from the Lora range east of Sehora) that all the most important existing mines are sunk. (3) "All the iron-workings," says Mr. Hackett, "are situated near the base of the (Lora) group, where the quartz bands (4) are absent, and the rocks consist almost entirely of micaceous iron, or mixed with a few bands of clay. The Janli mines are so situated, as also those of Mangela, and at Agarja in the Majhauhi hills, and also in the hills west of the 'marble rocks.' This band of rich iron appears to be very constant in the section, but, being softer than the rocks above, is mostly worn away, and covered by the alluvium or debris from the ridges of the harder rocks; but that the band exists is shown by the pieces of rich iron-strewn along the line." (5)

A few workings in the Majhauhi hills (near the western edge of the map) are situated in rocks of the Bhitri group, but these are of very secondary importance. (6)

Probably the most extensively worked cluster of mines in the district are those situated in the group of low irregular hills south of Sarroli and Majgaon (8 miles south-east of Sehora), and as the iron-bearing strata are exposed there more clearly, and on a larger scale, than in any other localities that I have visited, it will be convenient to take that neighbourhood as a starting point in any detailed descriptions.

The hill half-a-mile south of Agarja (4 miles west-south-west of Sarroli) appears to be formed entirely of iron ore. The strata have a low irregular dip towards the south. The highest beds, i.e., those on the south side of the hill, where there are numerous pits, are of evenly laminated micaceous iron, interbedded with occasional argillaceous layers. The rock is so soft that it can be powdered between the fingers, and is simply dug out with ordinary *kudalis*. But the greater portion of the ore, constituting the lower beds, is schistose hematite, which is harder than the micaceous iron, although easily worked on account of its fissile character. Numerous pits have been sunk into it also. There is a thin skin of laterite on the top of the hill, which is, in great part at least, and I believe wholly, due to alteration of the iron-schist *in situ*.

As this hill is about a third of a mile long, flat-topped, and wide, and not far from 100 feet high, the quantity of ore available by open workings, with free drainage, is enormous. As a very rough estimate, the cubic contents of the hill may perhaps be taken at $600 \times 450 \times 30$ or about four million cubic yards (7) which is equivalent to about fourteen million tons of ore. Even then if a liberal deduction be made for possible concealed bands of useless rock, the remaining figures will represent an immense amount of ore.

A sample of schistose hematite from the northern side of the hill yielded on analysis—

| | | |
|---------------------------|-----|--------------------|
| Ferric oxide | ... | 97.54 = Iron 68.28 |
| Phosphoric acid | ... | .12 |
| Sulphuric acid | ... | traces |
| Sulphur | ... | traces |
| Loss on ignition (8) | ... | .89 |
| Ignited insoluble residue | ... | 1.21 |
| Alumina and undetermined | ... | .24 |
| | | 100.00 |

In the low ridge which runs westward from Agarja a band of hematite schist, several yards thick, is visible along the crest.

(2) *Fide* p. 100.

(3) Here, and subsequently, in reference to native operations, I use the word 'mine' to express an excavation where ore is extracted, irrespective of its form. Underground workings are rather the exception than the rule, the majority of the excavations being irregular open pits.

(4) *Fide* p. 100.

(5 & 6) *MS. report, 1870-71.*

(7) The product of the dimensions of the hill is divided by 2, to allow for the slopes and irregularities.

Elsewhere the rock is obscured by talus, &c. Except, however, near the base of the southern slope, where pieces of ferruginous sandstone are strewn, the debris on the ridge is entirely of hematite schist, so that considerably more ore may exist than is actually seen. The ridge is perhaps 40 to 50 feet high, and comparatively wide, with gentle slopes. Even if the hematite band is not thicker than the exposed strata, a large amount of ore is available in the ridge. The dip, as seen about half-a-mile west of the village, is to the south at 40°-50°.

In the hills south-east of Agarja, I observed runs of ore in two or three places, but nothing of much importance. At the western end of the Jhiti ridge some limonite schist is seen, dipping S. 20° E. at 40°, but no good section is exposed. This, as well as other Bijawur hematite ores, which are of rather unfrequent occurrence, may possibly be due to hydration of hematitic strata near the surface. At the southern base of the hillock just west of Kurumukur, jaspery quartz schist interbanded with micaceous iron is seen. The hillock is capped by laterite, and similar rock is to be seen in some of the hills to the north-east of the same village. These hills are low and featureless, with little or no other rock visible. It is not at all improbable, however, that the laterite is due to superficial alteration of iron ore, and that there is a considerable, perhaps a large, quantity of the latter in the hills in question.

There are two low hillocks close to Sarrolli, one three-quarters of a mile somewhat south of west, and the other a mile south-south-west from the town. The former of these is composed of schistose hematite and micaceous iron, the beds of which have an irregular strike, corresponding on the whole with the direction of the hill, and an uncertain dip at high angles. There is a skin of laterite in places due, I have no doubt, to superficial alteration of the ore.

The northern part of the other hill is also composed of iron ore, which has an irregular dip, apparently towards the south as a whole. The southern part of the hill is formed of hornstone. The lower beds of ore, i.e., those in the most northern part of the hill, are of hard micaceous iron passing into schistose hematite, while the upper strata are of soft, crumbly, finely laminated micaceous iron, with some interbanded argillaceous layers. It will be observed that the section here is similar to that in the hill half-a-mile south of Agarja—soft crumbly ore above and harder beds beneath—and I do not think there can be much doubt that the strata in the two localities belong to the same horizon. There are two rather large excavations in the upper beds; that to the south-east is known as the Sarrolli mine, and that to the north-west as the Partabpore mine (from a village close by which is not marked on the map).

As a rough estimate of the amount of ore available by open workings, with free drainage, in the Sarrolli hills, the cubic contents of the northern may perhaps be taken at $\frac{600 \times 150 \times 15}{4}$, or about 500,000 cubic yards, and that of the iron-bearing part of the southern at $\frac{300 \times 200 \times 17}{4}$, or about the same amount. This is equivalent to about 1,700,000 tons of ore in each hill, or say three and-a-half million tons in both together. In this estimate, as in that for the hill south of Agarja, no account is taken of the ore which would be raised from open workings beneath the level of the surrounding country. From such workings an immense amount of ore could be obtained.

A sample of the crumbly micaceous iron from the Partabpore mine, taken as it was being loaded on to buffaloes for transmission to the neighbouring furnaces, yielded—

| | | |
|-------------------------------------|-----|--------------------|
| Ferric oxide ... | ... | 92.21 = Iron 64.55 |
| Phosphoric acid ... | ... | .07 |
| Sulphuric acid ... | ... | trace |
| Sulphur ... | ... | trace |
| Loss on ignition ... | ... | 1.86 |
| Ignited insoluble residue ... | ... | 4.50 |
| Lime, alumina, and undetermined ... | ... | 1.36 |

100.00

The harder ore from the north end of the hill gave—

| | | |
|-------------------------------|-----|--------------------|
| Ferric oxide ... | ... | 97.16 = Iron 68.02 |
| Loss on ignition ... | ... | 1.30 |
| Ignited insoluble residue ... | ... | .89 |
| Undetermined ... | ... | .65 |

100.00

The largest iron mine in the district is that near Juall, somewhat less than a mile south-east of the village (3 miles south-east of Sarrolli). The ore is a semi-ochreous hematite, in which a slightly schistose structure is often apparent. Hematite with metallic lustre also occurs, but is quite subordinate to the more ochrey kind. The ore is interbanded with quartzose layers, which in some places greatly exceed the ferruginous part of the rock. In other places they are comparatively rare, and in the best ore they are still less common. These layers vary from a fraction of an inch to several inches in thickness. The beds are vertical, the strike, where best seen, being N. 40° E. A rough measurement showed the beds exposed to have a thickness of about 150 feet, but in estimating the thickness of ore, a deduction must be made as an allowance for the quartzose portion just alluded to.

The ore has been very largely worked, the mine being nearly 100 yards long by 50 yards broad, and perhaps 50 feet deep. I was informed by Mr. Olpherts' agent in charge of the mine, that it is not flooded in the rains; it is a sort of deep trench (the length of which coincides with the strike of the rock) in which water would accumulate if it did not soak away subterraneously, or evaporate, quicker than it entered. The surrounding country is an undulating one, and without actual levelling, it would be impossible to say to what extent free drainage could be depended on for more extensive operations.

It is from picked ore from this mine that Mr. W. G. Olpherts' 'metallic paint' is made, by grinding to an impalpable powder.

Some distance, perhaps a quarter-of-a-mile, to the north-east of the above mine, there is an old abandoned one. The ore exposed is not as rich as that in the mine now worked, and naturally so, as previous to abandonment all the best ore exposed would be removed. The beds dip E. 30° S. at 40°, the strike therefore being nearly the same as in the newer mine. Mr. Hackett considered the ore in both mines to belong to the same band, and one can scarcely doubt that such is the fact; but the ore is so soft that it makes no show at the surface, and hence cannot be traced along the outcrop. If the band is continuous, however, for even a quarter-of-a-mile only, with anything like the thickness it has in the present mine, a very large amount of ore is hidden beneath the surface.

An average sample of the Jallipore, taken as it came, and including the interbanded quartz yielded on analysis—

| | | |
|---|-----|------------------|
| Ferric oxide ... | ... | 75.09 Iron 52.93 |
| Phosphoric acid ... | ... | .10 |
| Sulphuric acid ... | ... | traces |
| Sulphur ... | ... | traces |
| Loss on ignition ... | ... | 1.52 |
| Ignited insoluble residue ... | ... | 22.32 |
| Manganese oxide, lime, and undetermined ... | ... | .30 |

100.00

By the aid of some picking, however, a much purer ore can be obtained. A sample assayed by Mr. A. Tween gave 96.86 per cent. of ferric oxide 68.50 of iron, and some of Mr. Olpherts' paint gave 97.10.

Before leaving the ores of this neighbourhood, I ought to mention that the hematite of Juall and Agarja, as well as of the hills close to Sarrolli, is most distinctly a bedded rock, having generally (except at Juall, where it is less strongly marked) a highly schistose character. Locally indeed the rock is crushed and re-cemented, and this crushing may have taken place along lines of faulting (probably merely local slips). But except in such very limited sense the ore is most certainly not a fault rock. The point is one of practical importance with reference to the probable persistency of the ore, and is alluded to, as the reverse has been previously stated.

The most prominent rock in the Lora range (east of Sehora) is a ferruginous siliceous schist, composed of alternating layers of micaceous iron and quartz, which is usually of a red jaspery type. The layers are of irregular thickness, varying from a small fraction of an inch to an inch and upwards. For want of a better name, and to avoid circumlocution in referring to it, this rock may perhaps be called jasper-hematite schist. If it were marked as an iron ore, the Lora range (as well as many other lines of hills) should be streaked with gold from end to end. But a large proportion of the rock contains too great an amount of silica to allow of its being smelted with advantage, more especially when ores practically free from silica are to be obtained in abundance. Only those places, therefore, are marked with gold in which I have myself seen good workable ore.

At the termination of the range north of Mangola, a band of jasper-hematite is exposed *in situ* along the crest. Lower down the slopes there is a talus of the same rock, amongst which pieces of micaceous iron 2 or 3 inches thick, or more, and free from siliceous layers, are not uncommon. But the beds are not exposed sufficiently for one to form an opinion as to whether there is any considerable quantity of ore.

The hill half-a-mile north of Gogra is formed mainly of jasper-hematite. Near the base of the southern slope there are a number of shallow ore pits, but they are only in talus, not in the rock *in situ*. The miners seek for the small bits of ore which can be used at once in the furnaces, and leave the large lumps, which would require the labour of breaking up. The ore is a manganesiferous micaceous hematite, containing a varying proportion of interbanded jaspery quartz. It is a siliceous ore, although not very highly so. As the manganesiferous band is entirely concealed beneath the talus, no estimate can be made of its thickness. Judging, however, from the large amount of debris, it seems probable that the thickness is considerable. As the loose ore must either lie directly over that *in situ*, or else have come down hill, and as the pits extend 20 or 30 feet (vertically) from the base of the hill, probably a large amount of ore is obtainable by dry open workings whether these be through a deep mass of talus or into solid rock.

The proportion of manganese varies much, as can be seen from the outward appearance of the ore. In some specimens of the micaceous iron, the presence of manganese is scarcely apparent to the eye; in others, the ore shows by its dark colour, that it contains a large amount, and in the highly manganesiferous portions pisolomelane occurs in irregular segregations. A carefully

(8) This and the other then, therefore, includes of the hydrous ores,

(9) Memoirs, Geol. Surv. of India, Vol. II, p. 278.

(10) These to the west being to the village Gogra, and those to the east

Darwaz.

(11) 600.

chosen average sample made up of a large number of small pieces taken from different pits, yielded—

| | | |
|--|--------|------------|
| Ferric oxide | 64.35 | Iron 44.43 |
| Manganese (with traces of cobalt) | 13.25 | |
| Oxygen | 9.33 | |
| Phosphoric acid | 27 | |
| Sulphuric acid | 0.5 | |
| Sulphur | traces | |
| Ignited insoluble residue | 0.55 | |
| Lime, alumina, water, and undetermined | 4.78 | |
| | 100.00 | |

The manganese exists, in large part at least, in the form of psilomelane, occurring in irregular segregation, or minutely disseminated through the rock.

The Gogra miners told me (and Mr. Hackett mentions the same thing) that the ore from these pits produces a hard steely iron, used for making edged-tools, &c., while that from the mines in the Sarroli neighbourhood yields a soft iron, used largely for *karra* (shallow basins for making *chuppatis*, in &c.) The difference is no doubt to be attributed to the manganese in the former.

The ridge running eastward from Kuthola (1 mile south-east of Seshora) is formed mainly of jasper-hematite. At the gap where the railway passes, the strata dip at a high angle towards the south. In the low hill just west of the railway station (Seshora road), the beds in which seem to be higher in the section, as the rocks actually lie, than those just mentioned, manganiferous hematite schist, with psilomelane, is visible. The rock is more earthy and impure-looking than that at Gosulpore, which will be described presently, and contains a considerable amount of inter-banded jasper and quartz. No great thickness is exposed, but the outcrop is of some importance, as indicating the position of the manganiferous band.

Where the Deccan road passes the end of the ridge, jasper-hematite with hornstone is visible *in situ*, and pieces of psilomelane, &c., are scattered about.

On the northern slope of the hillock, about 300 yards N. 15° W. from the Dek Bungalow at Gosulpore, a strong band of manganiferous micaceous iron outcrops. In a little *nalla* at the foot of the hill the following section is exposed:—

| | Feet. |
|------------------------------------|-------|
| Clay-slate, seen about | 50 |
| Somewhat ferruginous quartz schist | 5 |
| Obscured | 20 |
| Manganiferous micaceous iron | 15? |
| quartz schist... | 5 |
| micaceous iron, seen | 35 |

The total thickness of ore actually seen being about 50 feet. The section is given in descending order, as the rocks lie, the dip being about 60° to N. 30° W.

The hillock just mentioned forms the eastern extremity of a low scarp, running from Gosulpore to W. 30° S. The scarp is capped by several yards of rock laterite, but lower down the slope (which faces to N. 30° W.) the manganiferous band outcrops in several places. It is fairly seen at intervals for about a third of a mile, and reveals its presence more obscurely, by occasional small outcrops, and by loose fragments, for at least a quarter of a mile more. As in the first third of a mile, the outcrop is well above the plain (averaging perhaps 20 feet or so), there is, unless the band thins out considerably immediately westward of Gosulpore, which is not likely, some hundreds of thousands of tons to be had by dry open workings, and probably some millions by going deep enough.

The appearance of the rock shows (as at Gogra) that the proportion of manganese is very variable. The greater portion of it, at least, exists in the form of psilomelane, occurring partly as linings to small cavities in the rock, and in irregular segregations and masses, some of which contain some cubic feet of mineral. I am somewhat inclined to think that the psilomelane is most abundant where the schist has crushed and re-cemented, psilomelane being the cementing material. A sample of the more manganiferous part of the schist afforded 18.02 per cent of manganese (with cobalt), while the psilomelane gave 83.20 per cent of available peroxide.

Reviewing the above details, it will be seen that manganiferous micaceous hematite has been found in several places along the southern side of the Lora range. One can scarcely feel much doubt as to there being a continuous band in that position. It is highly probable that the Gosulpore ore belongs to the same horizon, but whether it is a direct continuation of the same outcrop or not is more doubtful. The strata in the Lora range have a general dip towards the south-south-east at high angles, while the beds at Gosulpore dip N. 30° W. at about 60°. This may be a mere local feature, or it may indicate that the Lora and Gosulpore outcrops are on opposite sides of a synclinal flexure.

There does not appear to be any reason why the Gosulpore and Lora manganiferous ore should not form a suitable material for the manufacture of spiegel Eisen. Although part of the manganese occurs in distinct segregations, a large proportion of it is minutely disseminated through the ore.

On the slope of the hillock at Gosulpore above mentioned, a little below the outcrop of the manganiferous ore, there is a band of limonite not less than 15 feet thick. It can be traced westward for about the same distance as the other ore, to which it runs parallel. Some parts are very massive, the rock lying about in large blocks; others present a schistose appearance. At the time I took this to be a bedded Blawan rock, but I am not prepared to assert positively that it is so. Whether it be or not, a considerable quantity of ore (containing, however, a rather high

percentage of phosphorus) is to be obtained from it. It yielded on analysis—

| | | |
|---------------------------------|-------------|------------|
| Ferric oxide | 81.57 | Iron 57.10 |
| Phosphoric acid | 1.89 | |
| Sulphuric acid | 0.00 | |
| Sulphur | traces (10) | |
| Loss on ignition | 10.91 | |
| Ignited insoluble residue | 4.08 | |
| Lime, alumina, and undetermined | 1.75 | |
| Total | 100.00 | |

—Records of the Geological Survey of India.

SERICULTURE.

SERICULTURE IN BENGAL.

From G. N. BARLOW, Esq., C.S.I., Commissioner of the Bhagulpore Division and Sonthal Pergunnahs, to the Secretary to the Government of Bengal, General Department, No. 947 Ct., dated Camp Boaliore in Sonthal Pergunnahs, the 17th February 1883.

WITH reference to paragraph 11 of the Government Resolution on the General Administration Report of this Division for the year 1881-82, I have the honour to submit herewith copy of a very exhaustive report, and its enclosures, furnished by Mr. Pproh, the Collector of Maldah, on the subject of silk manufacture in that district, and to state that I have nothing to add to what he has said.

2. As for the disease of the silkworms and its cure, the Deputy Commissioner of Sonthal Pergunnahs reports that tassar silkworms are subject to epidemic disease. The crop of August and September last have in many places been a failure, the young worms dying from a disease locally known as "chhernee," a form of cholera or diarrhoea which killed them in four or five days. As a prophylactic and antidote the Sonthals use the root of a plant called "chowla." The root is finely powdered and mixed with cold water. The leaves on which the worms feed are well saturated with this liquid, which is said to prevent the disease and cure the silkworms that eat the leaves so treated. Very few of those attacked recovered. The Sonthals, however, have much faith in this remedy as a preventive.

3. The Sub-Divisional Officer of Banka reports in similar terms regarding the state of the tassar worms in his district. He adds that no satisfactory cure for the disease is known.

From R. PORCH, Esq., Collector of Maldah, to the Commissioner of the Bhagulpore Division, No. 991, dated Maldah, the 2nd February 1883.

WITH reference to your No. 391G, dated 28th November 1882, regarding measures to prevent epidemic disease among silkworms, and the alleged decline of the Indian silk industry in consequence of such disease, I have the honour to inform you that the subject seems to have been noticed in a confused way in the General Administration Report for the Bhagulpore Division for 1881-82.

2. It is a large subject to deal with, and the following divisions of the subject must first be kept in view:—

(1).—The Indian mulberry silk industry under the European system of reeling and supervision—

(a) by the English firm Watson & Co.;
(b) by the French firm L. Payen & Co., and the European or Western market for such silk.

(2).—The Indian mulberry silk industry as conducted under the native system of reeling, and its market in the east; also as to mulberry silk, the Maldah mulberry cocoons reared on the immature shrub mulberry leaf, and the Midnapore mulberry cocoons reared on the mature mulberry-tree leaf.

(3).—Cocoons of other than mulberry silkworms, viz., tassar silk cocoons, eri silk, &c.

3. As to the last, tassar, &c., though such cocoons are procurable in this district from the *boir* and other trees, and though such cocoons could be reared, no such industry could be successfully developed in Maldah side by side with, and in competition with, even the most inferior kind of mulberry silk cocoons industry, because of the superiority in every respect of the mulberry silk industry at every stage, viz., growth of leaf-feeding worms, spinning cocoons, reeling the silk into thread, throwing such thread into organzine. If the alleged decline of the tassar silk industry is referred to in the letter under reply, then I may say from general enquiry that it does not appear that establishing exhibitions would benefit the tassar silk industry, for the decline is due to the hitherto rather unworkable character of the tassar cocoons. Owing to the difficulty of spinning the tassar cocoons, and the still greater difficulty of reeling the tassar cocoons for that reason, profits from this industry are low, and there are no inducements to embark or to retain capital in such an indifferent investment. The decline appears to be due to the tassar industry being commercially rather a failure, and not to any particular deterioration from disease of the tassar worm.

4. Returning to the subject of the mulberry silk industry, in which this district is greatly interested, the superior branch of it—the European supervised filature silk—this is not prospering. It is at best a very precarious industry owing to foreign causes, viz., state and competition of the other foreign silk-producing centres in China and Japan, and in the European or Western silk market, aggravated at times by the demand there is for the native reeled silk (Khangru) for the local Eastern silk market, such demand being able to a profit to take up thousands of maunds of cocoons, and so to enable the native silk trade to put pressure on European firms, and send up the price of cocoons to a limit that is unprofit-

able, or just enable Europeans to keep their flatures open, unless a favourable turn in the European silk market helps them.

5. The native silk industry is prospering. Mulberry cultivation is extending. Rents for mulberry lands sub-ryot are enormous, viz., from Rs. 15 to Rs. 25 a beegha. In a khas mahal I fixed the Government rate of rent for such land at one rupee a beegha, but it was reduced by the Board of Revenue to 12 annas a beegha. In its agricultural aspects, and as regards the easy profits made by natives from the native mulberry silk industry, the industry must be considered as brisk, prosperous, flourishing.

6. Under such circumstances, inferior and deteriorating as the Bengal silkworm is, exhibitions are unlikely to bring about any benefit, because the natives interested in the trade will not accept any radical change of custom in the present state of affairs as to silk. The Bengal worm suits its circumstances; it eats little comparatively, and thrives on the immature or shrub mulberry leaf, which is renewed at every cutting; it is less troublesome in rearing, and spins often (multivoltine). The silk-thread reeled is therefore wanting in wiriness and is very endy, which makes Bengal silk, as it is, an abomination to the European silk thrower, viz., preparer of organzine. The natives do not care about that, so long as the industry goes on according to custom, and they can easily raise and dispose of the frequently yielded shrub mulberry-fed cocoon, either at forced-up prices to the European silk companies, or reel it off themselves and dispose of it as a still coarser silk-thread than European Indian silk, viz., the "Khangru" silk for the Bombay silk-weaving mills, and eventually for the Barmah and other markets. In Midnapore the Bengal silkworm, it seems, is fed on mulberry-tree leaf, and produces a better cocoon which gives a more wiry thread and less endy thread in reeling, owing to the mature nature of the leaf fed on by the silkworm, viz., the leaf of the full-grown mulberry-tree.

7. Those engaged in the mulberry silk industry in this district understand these matters, and are wealthy enough to bring about necessary reforms in the industry, if it would pay them to do so; but any change, even if obviously advantageous, is disliked, and is suspected by the natives. They require no inducement from exhibitions for the improvement of the silk industry. With reference to the actual causes of the existing defects in this industry, it may be remarked here that from the circumstances of the country, the scantiness of fodder, the slender resources of the ryot, and the narrow area of his industrial effort, a comparatively puny breed of cattle answers his purpose better than a large, strong, and more costly stock: so, too, as regards the breed of the Bengal silkworm, with all its defects.

8. Moreover, if anything could be done in this way, the wealthy European firms, who have so great a stake in the Indian silk industry, would have worked in this way with success for the instruction of their silk gomastahs and cocoon rears; but they have failed to alter the custom of the country, bad as it is in this respect, though they have repeatedly made such efforts.

9. The European supervised silk industry in India is a very precarious investment, but may be profitable to wealthy firms that can stem over a succession of bad years. Indian mulberry silk, from the nature of the cocoons, when reeled, is wanting in wiriness and is endy, and is hard to throw into organzine. If it could be better wound and be more wiry and less endy, the European supervised silk industry in India might hold its own against the most adverse of European markets.

10. If the European supervised silk flatures were closed, the native silk industry would still thrive for a long time, but undoubtedly such collapse would recoil upon it, and be disastrous to the native silk industry, which is so largely subsidised and indirectly guided by European capitalists. Without that capital and guidance and support, the native silk industry would, it is believed, become very precarious and collapse after a time.

11. Any glut in the native-reeled silk market, viz., in the demand for Khangru silk brings down the price of the cocoons and sends the ryots with their cocoons to the European silk company's agents. There has been such a decline this year in the demand for Khangru silk, which, with the abundant yield of cocoons in the last *bundh*, has placed cocoons at a price that keeps all the European supervised flatures actively at work so far as spinners are to be had.

12. Mulberry has been this year slightly in excess of demand. No worms were lost for want of food. A little mulberry was lost through not being required. The excess of the mulberry crop was owing to the moisture from the lateness of the last rains. The last cocoons were therefore a wonderfully fine crop. There has been rather a glut in the native silk market owing to the cheapness of cocoons and other causes in previous seasons (viz., over-produce, because many of the European flatures did not work owing to high prices of cocoons), and natives therefore now reel their cocoons in their small flatures at home rather than sell them. Cocoons are three rupees a maund cheaper than usual.

Native silk traders and owners of small flatures have engaged spinners; and though the European firms can get cocoons at prices that pay to manufacture silks they cannot get spinners, and so many "gains" or "basins" and reels remain unused.

13. The price of Khangru silk is from Rs. 11 to Rs. 12 per seer of 81 *sloca*; cocoons from Rs. 29 to Rs. 30 per maund of 80 *sloca*; "Chapain," or the silk refuse after reeling, sells at Rs. 50 a maund.

14. At the minimum, 12,000 maunds of cocoons are reared. Of these about 8,000 are reeled by natives and about 4,000 are reeled for the European silk companies under European supervision. The return is much in excess of this generally.

15. Certain letters that appeared in the *Indian Agriculturist*, in the last quarter of 1887, on this subject, appear to me to be very absurd and quite beside the mark. Rack-rents, or the high rates of rents paid for mulberry land, have not in the least affected the mulberry cultivation for the silk industry, and do not affect

the question. It is a mere question of division of agricultural profits between the landlord and the tenants of different degrees, where the estates are permanently settled. There is no restriction of mulberry cultivation affecting the silk industry. Competition rents do not prevail among sub-ryots, and rates have risen proportionate to the expansion and profits of the native silk industry. The introduction of such topics as Sunday work and immorality of the factory people in European silk factories is equally absurd and irrelevant as regards the prosperity of the industry, though the latter is much to be deprecated and put down, if it is so, in other and higher interests.

16. A copy of a report sent from this office to the Secretary of the Economic Museum, Calcutta, regarding the silk industry, of this district, No. 155, dated 8th June 1880, is herewith forwarded.

From R. PONCE, Esq., Magistrate and Collector of Maldah, to the Secretary to the Economic Museum, Calcutta, No. 155, dated Maldah, the 6th June 1880.

I HAVE the honour to submit the following information regarding the silk industry in the district of Maldah.

2. The following published records may be referred to:—

(a).—The history, antiquities, topography and statistics of Eastern India, as surveyed by Dr. F. Buchanan Hamilton, (1807-1814), collated by Montgomery Martin, in three volumes, volume II, pages 559-572.

(b).—Report of the proceedings of the East India Company in regard to the trade, culture, and manufacture of raw silk, submitted in 1836.

(c).—Silk in India, compiled by J. Geoghegan (1873), section I, paragraphs 5, 27, 28, 29, 31, 32, 33, 34, 35, 36, 52, 54, &c.

(d).—Dr. W. W. Hunter's Statistics of Bengal, volume VII, pages 94-98, district of Maldah (1876).

(e).—In connection with subject, "The Wild Silk of India and the uses of tassar and other wild waste," have recently been noticed in the Secretary of State's despatch No. 104 (Statistics and Commerce), dated 11th December 1879, to the Governor-General of India in Council.

3. The following notes on the present state of the silk industry in Maldah are extracted from the Annual Administration Reports of the district of Maldah submitted by me in 1878-79 and 1879-80 to the Commissioner of the Bhagulpore Division (extract from the Annual Administration Report of the district of Maldah, 1878-79, paragraphs 18 to 26; and paragraphs 57 to 60 inclusive; extract from the Annual Administration Report of the district of Maldah, 1879-80, paragraphs 19 to 20 inclusive).

4. (1878-79) The cultivation of mulberry farmed well and the crops were not far below the average. The year was very favourable as to weather for the production of cocoons, and the cocoon rears, who had to buy more mulberry leaves than in other years owing to the abundance of silkworms, could not make the business very profitable on account of the dearthness of the mulberry leaves. The dullness of the silk market has caused the closing of several large concerns conducted by European agency. The native flatures have been doing a brisk business in their coarse silk.

5. The market for silk fluctuated very much. Last season good European flature silk sold at Rs. 18 per seer of 72 *sloca* weight, and at the end of the season at Rs. 14 and Rs. 14-5 per seer. The native manufacturers are almost out of the Calcutta market. The natives reel an inferior coarse silk called Khangru, which is in great demand for the Bombay market. Nearly three-fourths of the cocoons reared in this district are reeled into this inferior silk in the small native flatures. It commands a uniform rate of between Rs. 11 and Rs. 13 per seer of 80 *sloca* weight, and the price of cocoons is regulated by the market rate for the native silk; so that European manufacturers have frequently to work at rates which leave them no margin for profit, and unfrequently they have to work at a loss (as they sell in the Calcutta and home market) and this they do simply to keep their workmen together.

6. The total quantity of cocoons reared in the Maldah district is between 38,000 and 40,000 maunds yearly; of this quantity, about 11,000 to 12,000 maunds are reeled into good silk for the Calcutta and home markets by European manufacturers, and the balance is reeled into Khangru by the natives, chiefly for the Bombay market. With regard to the quantity of cocoons, the produce per 80 *sloca* maunds of cocoons when reeled into good silk is on an average about 2 seers 4 chittacks of silk of 78 *sloca* weight. When reeled into Khangru a maund of cocoons yields nearly 2 seers 14 chittacks to 3 seers produce of 76 *sloca* weight.

7. The causes which affect the silk trade, and consequently the manufacture of silk, are the failure of the crop of cocoons, which is caused by extreme of heat and cold, by too much sun and cloudy weather, when the worms are in their last stage when they are spinning their cocoons, and also by the want of opportune showers for the mulberry. The market for silk is generally influenced by the result of the crops in France, Italy, and China, for when the cocoon crops are good in these countries, the market for India silk is, as a rule, very bad. The Italian, French, and China cocoons are far superior in quality to the cocoons reared here, and the silk is consequently of a better quality than Indian silk, which, as a natural consequence, is not in demand when large quantities of superior French, Italian, and China silk are procurable. The only improvement in the European flatures has been the substitution of steam for boiling the water in the basins, which formerly used to be done with wood fires, as the natives still do.

8. No uniform price is ever established for the purchase of cocoons; the several different qualities sell at different prices. To be able to judge of the different qualities of cocoons, requires great

practice. The system of purchasing cocoons followed by Europeans is as follows:—

9. The gomastah at each of their factories is under a contract to supply them with silk, and to be paid for the quantity of silk reeled from the cocoons they supply, and not for the cocoons themselves. They receive orders from time to time to make silk at such and such a rate per seer, the profit and loss on the cocoon purchasers being their own. They are not bound to supply their employees with silk if they cannot manufacture it at the orders they receive from time to time, but they are bound always to work to order, as the orders they receive are generally regulated by the state of the cocoon market; if the silk market is good they supply large quantities of silk and make a profit for themselves, as the orders they receive are liberal; but when the silk market is bad, these orders are restricted, so that they can only supply a small quantity, and that by picking and purchasing small quantities of cheap cocoons. Messrs. Watson and Company manufacture in this way through gomastahs who deal with the cocoon producers, but the French company, Messrs. Louis Payen, deal direct in cocoons with the ryots, and take leases of land in the mulberry-growing tracts in order to facilitate purchases of cocoons. The average price of cocoons during the season 1877-78 was about Rs. 35 per maund, and in season 1878-79 about Rs. 27 per maund. There are four kinds of refuse from cocoons, viz., chassam, waste chassam (native name gudhar), cocoons that will not wind (topah), and reel pickings (sawa). Good chassam sold at Rs. 120 to 140 per maund in 1877-78, and at Rs. 100 to 110 per maund in 1878-79; gudhar at Rs. 30 to 33 and Rs. 28 to 24 per maund; topah at Rs. 15 to 18 and Rs. 12 to 16 per maund; sawa at Rs. 65 to 70 and Rs. 56 to 60 per maund.

10. There are altogether six European filatures in this district, working a total of about 600 reels. Of this number, 100 are turned by steam-power, and the rest by the manual labour of boys. The total output of these filatures is about 480 maunds of silk yearly.

11. There have been no changes in the manufacture or mode of doing business in silk by Europeans or natives. At present the prospects of silk are very bad for European factories owing to the depressed state of the market, which has fallen of late years with each successive war in Europe. Manufacturers have no inducement for working their factories, as sales at a profit or even at cost prices are scarcely possible, while the stock of silk on manufacturers' hand is already very large.

12. Messrs. Watson and Company are manufacturers of raw or unthrown silk for sale as such in the Calcutta and the home market, and their business is entirely dependent on the market rate for raw silk. Messrs. Louis Payen and Company manufacture the raw silk in Bengal, and ship it to France for their throwing mills at Lyons; they are therefore to some extent independent of the market rate as regards the success or profit of their manufacturing operations.

13. The principal silk factories are the following:—

| | |
|--------------------------|----------------------|
| (1) Jalalpur ... | Messrs. Watson & Co. |
| (2) Sadra or Ghabari ... | Ditto. |
| (3) Baraghar ... | Ditto. |
| (4) Mahodipur ... | Ditto. |
| (5) Haripur ... | Ditto. |
| (6) Bholahat ... | Messrs. Louis Payen. |

Besides the European concerns, there are numerous native silk filatures in every village throughout the mulberry-growing area of the district, viz., the centre of the district.

14. The following are the different descriptions of silk pieces and silk and cotton pieces manufactured by natives at Sahapoor, Shawandal and Raipoor, and at other places in Shibgunge:—

Silk fabrics (Garad-cora, &c.)

| | | | |
|-----------------------|-----|-----|----------|
| 1. Majlahar ... | ... | ... | Pattern. |
| 2. Kalintarakshya ... | ... | ... | " |
| 3. Chandara ... | ... | ... | " |
| 4. Bulbel Chassam ... | ... | ... | " |
| 5. Mayur Kanti ... | ... | ... | " |
| 6. Dhup Chaya ... | ... | ... | " |
| 7. Other colours ... | ... | ... | " |

Silk and cotton mixed fabrics (Ilachi marru, Siraja, &c.)

| | |
|----------------|---------------------------------|
| 1. Ilachi, ... | { 1 Gulbadan. |
| 2. Masru ... | { 2 Katar of numerous patterns. |

15. These are generally woven in pieces from 24 to 25 feet in length, and their value varies according to texture from Rs. 10 to Rs. 25 a piece. The raw spun silk is thrown by the weavers and others, mostly women, for weaving. Clothes suited for native wear are also largely manufactured in the district, chiefly at Shibgunge.

17. (1878-80). Mulberry is mostly cultivated in thanas English Bazar, Kalachuk, and Shibgunge. This area greatly suffered from the flood in August 1879, and the mulberry crop then in leaf was destroyed; but after the flood had subsided, the plants revived, and the temporary injury was so far compensated as to be little felt.

18. The silk business was rather brisker than last year. Some of the silk filatures managed by English firms, that had stopped working in 1878-79 owing to the dullness of the market, were re-opened during the year 1879-80.

19. Review of silk manufacture in Maldah during the last five years.—The silk industry in the district of Maldah was about the same in 1874-75 and 1875-76. The prices of Bengal raw silk in the European market kept very steady during the years 1873-74, 1874-75, 1875-76.

20. Since the great fall of 1874, which brought down the value of European and native manufactured silk to nearly half the former price, ryots of cocoons have been complaining of losses. They no longer make the large profits of former years. They do not, however, lose when there are good crops. The heavy

loss the mulberry cultivators, who have not a certain market now for their mulberry, owing to the smaller number of worms reared, and also owing to the failure of the worms, which of late have become very frequent. The cause of the decrease in the quantity of worms reared is thus explained. Formerly rearsers, when losing their worms in two or three seasons, made such profits from cocoons in the seasons in which the worms thrived, that it more than compensated for the losses of bad seasons, and left them at the end of the year with good profits. Now the profits on good seasons are so small that they scarcely make up for the losses in bad seasons, and for this reason many rearsers keep only the quantity of worms which they can feed with their home-grown mulberry without buying any from the mulberry cultivators. Some mulberry cultivators have therefore given up growing mulberry.

21. The number of families in this district whose occupation it is to rear worms may be reckoned at 20,000. They raise in the whole year about 1,20,000 maunds of cocoons, worth now about 24 lakhs of rupees. Mr. T. Price, formerly of Boroghrah Silk Factory (Messrs. Watson and Company), informed me that about 40,000 maunds are reeled in Maldah (see last year's report). Dr. W. W. Hunter, in the Statistical Account of Bengal (Maldah), volume VII, page 96, gives the quantity of cocoons reared at Maldah, and reeled or exported raw, as 60,000 maunds, worth about Rs. 18,60,000. From the late Mr. L. Gay of Bholahat (Messrs. Louis Payen and Company) and from other sources, information was obtained that the quantity of cocoons reared in the district of Maldah, and reeled or exported raw, is about 1,20,000 maunds, worth now about Rs. 24,00,000. This seems to be more correct than the previous estimates. There are about 35 square miles of land under mulberry cultivation in the centre of the district. The yearly average cost of cultivation for one beegha of land is Rs. 25, and the yearly average yield of leaves 60 *beegas* or loads of one maund weight each, the average price of the load being 12 annas, giving Rs. 45 a beegha. This would show that the mulberry cultivator is still doing well, but unfortunately he does not always find a market for the leaf, and he has to cut it when ready all the same; this occasionally causes him loss.

22. One-seventh part of the cocoons are bought by European manufacturers; the remainder are bought either by native manufacturers, or are reeled into silk by the rearsers themselves, who most of them have one or two reels. The total number of reels in this district is at least 10,000. The silk reeled by natives is sold at the Aminjunge and Sodhukapur *hants*, and at Bholahat *sahi* or mart. It is also bought in the villages by the *dahals* or brokers. The purchasers of native silk (Khangru) are *mahajans* from Bombay, Benares, Delhi and other up-country places. Some is bought by the corah manufacturers of Mirzapore (in the district of Moorshedabad) and Benares; some also is used in home manufacture for corahs, masru, and other kinds of cloths. About a century ago some seven thousand looms, and in 1810 about 4,000 looms were employed in the manufacture of these different sorts of cloths, but for several years they have been gradually disappearing. It is said that about 700 looms are now worked. The masru, which used to employ the largest number of looms, is a cloth of mixed silk and cotton, the warp being native-wound silk, and the wool a fine European made cotton.

23. There are in this district six filatures belonging to Europeans, which contain about 800 basins (gals), and give work to about 2,000 people. Men, women, and children are employed in them. Some filatures from other districts are partly provided with cocoons from Maldah during the November and March seasons, and the total amount of silk manufactured by Europeans out of Maldah cocoons is about, according to the late Mr. L. Guy of Bholahat, 1,000 maunds or 80,000 pounds. The silk reeled by natives amounts to about 8,000 maunds or 480,000 pounds. The total number of people in this district to whom silk gives employment either by mulberry culture, worm-rearing, or silk-weaving or silk and cotton weaving, may be estimated at 300,000. The year is divided into three great "bunds," viz., crops or seasons, with small intermediate seasons as follow:—

| Species of mulberry moth. | | Bombyx Mori. | |
|---------------------------|--------------------------|---|--|
| November ... | { Agrahani (chief) } ... | Deal worm, Bombyx fortanatus (Chota Palu), and Bombyx Textor (Bora Pahu). | |
| | { Falgoun | | |
| March ... | Cheltre (chief) ... | Deal worm, Bombyx fortanatus, and Nistri or Madrasli worm, Bombyx orasi. | |
| | Bhysaki ... | Nistri or Madrasli worm. | |
| | Joyti ... | Bombyx orasi. | |
| | { Asari (chief) | Nistri or Madrasli worm. | |
| July ... | { Sraban ... | | |
| | { Bhaduri ... | Bombyx orasi. | |

24. The manufacture of silk and silk fabrics and silk and cotton fabrics in the district of Maldah during 1877-78 was not less than in 1876-77, but at the end of 1878-77, that is, about March 1877, war between Russia and Turkey having become imminent, there was a heavy fall in the demand both in the European and Calcutta markets, and Bengal silk, which in January 1877 was selling in Calcutta at Rs. 25 and Rs. 26 a seer, fell in March to Rs. 19 and Rs. 20, being a fall of nearly 25 per cent. Since March 1877 prices remained steady up to the beginning of March 1879, when fears of a complication of European affairs caused a further fall which brought prices down to Rs. 15 to 16 a seer. The native industry, which is very large in this district, kept very steady throughout the year 1878-79, and the export of native manufactured silk and pieces was quite as large as during 1877-78, and was made, as usual, to Calcutta, Madras, Bombay, Nagpore, Allahabad, Benares, and

Delhi. The largest exports were made to Calcutta and Bombay. The native manufactured silk, called Khangru, is bought in its raw state by silk piece manufacturers from the above-named towns. The silk pieces worn in the district are corahs seven yards long by one yard wide, and are mostly shipped to Europe, where they are used for handkerchiefs, and longer pieces are used in this country for native dress (dhooties). There is also another fabric called Musara. The warp silk and wool cotton which is woven for up-country markets finds sale there only. Early in 1879 the prices of native manufactured silk were also influenced by the bad political news from Europe, but not quite to such an extent as the European-made silk. The rise and fall of price of native silk depends on the state of Indian markets more than on those of Europe.

25. During 1879-80 the "bundhs" were not good. There was a considerable failure. The cocoons that arrived at maturity were of average quality. The average price was Rs. 35 a maund of 80 sicca weight. The silk market continued much depressed owing to stagnation of business in Europe from the causes above quoted, which greatly affected the demand for silk. There was a slight improvement visible at the beginning of 1880, and prospects are now somewhat more hopeful.

26. Particulars of the best kinds of Maldah silk and mixed silk and cotton fabrics now made in the district of Maldah are entered in the two accompanying lists of 15 and of 21 specimens, forwarded in May 1880 to H. H. Locke, Esq., Secretary to the Economic Museum, Calcutta, and Secretary to the Bengal Sub-Committee for the Melbourne Exhibition, for the purpose of being sent to the Melbourne International Exhibition of 1880.

DESCRIPTIVE INFORMATION AND GENERAL REMARKS.

These silk fabrics are produced from the cultivated mulberry leaf, which after cutting, is fed on by domesticated pure and hybrid worms, which in about forty days, spin cocoons, which are reeled in the native filatures and thrown by the native weavers, and the warp is stretched on a few sticks stuck up in the open air, and is thence removed to the loom, where the pieces are woven.

The white dhuties are worn mostly by men; the coloured dhuties are worn by men, and as saris by women also.

No. 6, 7, and 8 are similarly made of the native reeled silk, and are used as wrappers, like chaddars, or are cut up and used by wealthy natives for chappans or coats.

The silk and cotton mixed fabrics, Nos. 9-15 warp of native reeled silk and wool of European-made cotton, are made in the same way and are exported to the North-West, where various articles of attire are made from them for men and women in the North-West and in Madras.

The thread is dyed, before the material is woven, with vegetable dyes.

The information given in Hunter's statistical account of Bengal, Maldah, volume VII, pages 94-98, holds good, though the industry has gone through some vicissitudes from falling market.

List of silk, and silk and cotton fabrics produced in the district of Maldah, and sent by the Collector of Maldah to the Bengal Sub-Committee for the Melbourne Exhibition.

LAMPLOUGH'S PYRETIC SALINE,

H. LAMPLOUGH, 113, HOLBORN HILL, LONDON, E.C.

“ ‘What on earth shall I take to Zululand?’ asked my friend Jim Law one day at Aldershot, when he had just received orders for South Africa, to start at forty-eight hours’ notice. I replied, ‘If you take my advice—and it’s that of an old traveller—you’ll not budge without a few bottles of ENO, even if you leave half your kit behind. I never am without these Salts, and, please the pigs, never intend to be.’ On his return I inquired, ‘Well, how about ENO’S FRUIT SALT?’ ‘My dear fellow, it was the best advice you ever gave; they saved me many an illness; and when I left Tugela, I sold the remaining bottles for ten times the original price!’ ”—*Lieut. Col.*

You can change the trickling stream, but not the raging torrent.

THE ART OF CONQUEST IS LOST WITHOUT THE ART OF EATING—DINNER ENGAGEMENTS—STIMULANTS—TOO RICH FOOD—LATE HOURS—INSUFFICIENT EXERCISE—EXCITEMENT.
 So—a gentleman writes: "When I feel out of sorts, I take a dose of ENO'S FRUIT SALT one hour before dinner or first thing in the morning. The effect is all I could wish." How to enjoy good food that would otherwise cause biliousness, headache, or disordered stomach—use ENO'S FRUIT SALT.

Civil and Mechanical Engineers, Contractors, Brass and Iron Founders,
Metal Merchants, &c.

*Forged and Cast Iron Work, Boilers, Machinery for Jute, Cotton and Rice Mills, Collieries, Indigo Concerns, Tea Gardens, &c.,
Contractors' and Brick-making Plant, and every class of Iron and Brass Work made to order.*

SOLE AGENTS FOR

Robey & Co's celebrated Portable and Fixed Engines and Machinery, Gwynne & Co's "Invincible" Centrifugal Pumps, Gould's Rotary Pumps, and Robinson's Patent Steam Traps.

IMPORTERS AND MANUFACTURERS OF EVERY DESCRIPTION OF STEAM ENGINES AND MACHINERY.

Robey & Co's Portable, Horizontal, Fixed, and Patent "Robey" Semi-fixed Engines, Combined Vertical Engines and Boilers, Land and Marine Boilers, Gould's Rotary Power Pumps, J. & H. Gwynne's "Invincible" Centrifugal Pumps, Hand, Lift and Force Pumps, Tangye's "Special" Steam Pumps, "Vauxhall" Donkey Pumps, Flour Mills, Saw Benches, Spencer's Hand Drilling Machines, Steam Pressure Recorders, Richards' Engine Indicator, Gifford's Injectors, Cooking Stoves, Fire-Proof Safes.

J. & H. Gwynne's "Invincible" Centrifugal Pump.
This Pump being arranged to swivel on the bed-plate may be fixed at any angle required. It does not require a foot-valve, being fitted with small an exhaustor and clack on discharge, which always keep it charged ready for work.

Robey's Combined Vertical Engine and Boiler.
This class of Engine is nearly twice as large as those of the same nominal horse-power of some makers. The Engine, instead of being fixed to the Boiler as is usual in Engines of the same class, is erected on a massive Cast Iron Standard which makes it quite independent of the Boiler.

These Ploughs have been expressly designed and manufactured for the use of the Ryots of India, whose special needs have been carefully studied in their construction. They embody all the qualifications for which the native made implements have hitherto been preferred, whilst being incomparably superior in strength, durability, and efficiency.

MORAE'S PATENT SUB-SOIL AND GENERAL PLOUGH

Stirs up the soil to three times the depth of a native plough, and leaves the good mould on the top. Goes through the dirtiest land without getting choked with weeds. Price, Rs. 15.

INDIGO AND TEA PLANTERS' IMPLEMENTS AND STORES.

ENGINEERS' TOOLS AND STORES OF ALL KINDS.

ALWAYS ON HAND A LARGE STOCK OF PLATE, BAR, ANGLE, TIE AND CORRUGATED IRON, STEEL, BRASS, COPPER, PIG IRON, FOUNDRY COKE, SMITHY COAL, FIRE BRICKS, AND FIRE CLAY.

 Catalogues on Application.

GOODALL'S Household Specialities.

A Single Trial solicited from those who have not yet tried these Splendid Preparations.

YORKSHIRE RELISH.

The Most Delicious Sauce in the World.

This cheap and excellent Sauce makes the plainest viands palatable, and the daintiest dishes more delicious. With Chops, Steaks, Fish, &c., it is incomparable. In bottles, at 6d., 1s., and 2s. each.

GOODALL'S BAKING POWDER.

The Best in the World.

Makes delicious pudding without eggs, pastry without butter, and beautiful light bread without yeast. In 1d. packets, 6d., 1s., 2s., and 5s. tins.

GOODALL'S QUININE WINE.

The Best and most Agreeable Tonic yet introduced.

The best remedy known for Indigestion, Loss of Appetite, General Debility, &c. Restores delicate individuals to health. At 1s. 1½d. and 2s. 3d. each bottle.

GOODALL'S CUSTARD POWDER.

For making Delicious Custards without Eggs, in less time and at half the price.

The Proprietors can recommend it to Housekeepers generally as a useful agent in the preparation of a good custard. GIVE IT A TRIAL. Sold in boxes, 6d. and 1s. each.

GOODALL'S GINGER BEER POWDER

Makes Three Gallons of the Best Ginger Beer in the World for Threepence.

The most valuable preparation for the production of a delicious and invigorating beverage. It is easily made, and is by far the cheapest and best Ginger Beer ever offered to the public. Sold in packets, 3d. and 6d. each.

GOODALL'S EGG POWDER.

Its action in Cakes, Puddings, &c., &c., resembles that of the egg in every particular. One penny packet will go as far as four eggs; and one sixpenny tin as far as twenty-eight. Sold everywhere, in 1d. packets; 6d. and 1s. tins.

GOODALL'S BLANCMANGE POWDER

Makes delicious Blancmange in a few minutes. In boxes at 6d. and 1s. each.

All the above-named Preparations may be had of all Grocers, Chemists, Patent Medicine Dealers, and Oilmen.

Proprietors: GOODALL, BACKHOUSE & CO, Leeds, England.

FREEMAN'S SYRUP OF PHOSPHORUS.

Nature's Great Brain and Nerve Tonic and the most wonderful Blood Purifier. The highest Medical Authorities say that it is the only Cure for Wasting Diseases, Mental Depression, Loss of Energy, and Stomach Complaints.

It is pleasant to the taste, and might be taken by the most delicately constituted. In the most enfeebled it builds up a NEW AND HEALTHY CONSTITUTION. One dose of this Remedy is equal to Twenty Doses of Cod-Liver Oil.

Thousands have been snatched from the brink of the grave by the timely use of FREEMAN'S SYRUP OF PHOSPHORUS. May be had of all Chemists and Patent Medicine Vendors, in bottles at 2s. 9d., 4s. 6d., 11s., and 33s.

NOTICE.

SUTTON'S SEEDS & CATALOGUES

MAY BE HAD OF DULY AUTHORISED AGENTS

IN EVERY PART of the WORLD,

INCLUDING—

The Proprietors, *Indian Agriculturist*, Chowringhee-road, Calcutta; the Great Eastern Hotel, Company, Limited, Calcutta; Messrs. Wilson, Mackenzie & Co., 13, Old Court House-street, and 1, Mangoe-lane, Calcutta. Orders received by Messrs. King, Hamilton & Co., Calcutta.

NOTICE.

In ordering through London Shippers, purchasers should be particular to stipulate for SUTTON'S SEEDS.

TESTIMONIAL.

From S. Jennings, Esq., late Vice-President of the Agri-Horti. Society of India

"With reference to your mode of packing seeds for export, I must say how much I was gratified with the system you were so good as to show me. During the whole of my long Indian experience, it was my constant regret that English packed seeds were almost invariably lower in germinating power than the American. After seeing the elaborate precautions you take in executing such orders as that of the Agri-Horti Society of India, I am by no means surprised to hear that you have been gratified by the receipt of so much testimony from the tropics as to the condition of your Seeds upon arrival."

OVER 450,000 FEET SOLD DURING 1881.

* Including 3,877 feet of main Driving Belts, of widths ranging from 13 in. to 60 in., are working in over 6,000 Mills and Works in Europe and America.

The following Tests (by Kirkaldy, of London) show the relative strength and value, compared with Leather.

| | Breaking Strain per Square Inch of Section. | Price per foot. |
|--|---|-----------------|
| Best Double Leather 8 in. Belting | 3,572 lbs. | 6s. 7d. |
| Gandy's 8 in. x 8-ply Cotton | 6,811 lbs. | 2s. 6d. |

THE GANDY BELT.

Any Length or Width
for Main Driving.

It is the best belt ever made for all purposes. Much Cheaper and Stronger than Leather. Thoroughly Waterproof, and not affected by temperature, clings well to the pulleys, runs true, and can be made any length without joints.

This Series of Belting (see engraving) was supplied in One Order to Messrs. John Crossley and Sons, Halifax, May 1, 1880, and continues to give entire satisfaction.

THE "GANDY" BELT.

GANDY'S Patent American Cotton Belting, can claim a superiority over leather belts in every particular: its cost being about half that of leather, while its strength and gripping power is at a double that of the best leather, as shown by repeated tests taken by Kirkaldy, of London. These tests are given above, to which special attention is directed. These "Gandy" belts are made of any width up to 72 inches, and any length up to 340 feet without joint, thus obviating the necessity of having two belts on the same pulley, a system of driving which is never satisfactory, as it is impossible to have belts of exactly the same tension; hence one or the other is always causing a stoppage. These stoppages are avoided by using Gandy's Patent Belts in one width. These Gandy Belts are made of the finest American Cotton Duck, specially prepared at Halifax for the purpose, and then put together and finished by Gandy's patented special Machinery and process to prevent stretching, and make them impervious to atmospheric influence. Possessed of advantages such as these, the universal adoption of Gandy's Belts can only be a question of time.

A SUBSTANTIAL GUARANTEE GIVEN WITH EVERY MAIN DRIVING BELT.

THE GREAT REMEDY FOR PRICKLY HEAT, INDIGESTION, HEADACHE, BILIOUSNESS, AND FEVERS.

The testimony of medical gentlemen has been unqualified in praise of

LAMPLOUGH'S PYRETIC SALINE,

As possessing elements most essential for the restoration and maintenance of health with perfect vigour of body and mind.

It is Effervescent and Tasteless; forming a most Invigorating, Vitalising, and Refreshing Beverage.

Gives instant relief in HEADACHE, RHEA or BILIOUSNESS, CONSTIPATION, INDIGESTION, LASSITUDE, HEARTBURN, and FEVERISH COLDS; prevents and quickly cures the worst forms of TYPHUS, SCARLET, JUNGLE, and other FEVERS, SMALLPOX, MEASLES, and NEUPTIC or SKIN COMPLAINTS, and various other altered conditions of the blood.

Dr. PROUT:—"Unfolding terms of immense benefit to mankind."

Dr. MORGAN:—"It furnishes the blood with its lost saline constituents."

GOVERNMENT OFFICIALS AND PLANTERS caring for the welfare of their employees should note its value as a specific in Fever cases.

Dr. J. W. DOWLING:—"I used it in the treatment of forty-two cases of Yellow Fever, and am happy to state I never lost a single case."

Dr. W. STEVENSON:—"Since its introduction the Fatal West India Fevers are deprived of their terrors."

HIS MAJESTY'S REPRESENTATIVE the GOVERNOR OF SIERRA LEONE in a letter of request for an additional supply of the Pyretic Saline, states:—"It is of great value, and I shall rejoice to hear it is in the houses of all Europeans visiting the tropics."

To be obtained of any Chemist or Drug Store, in Patent Glass-stoppered Bottles, 2s. 6d., 4s. 6d., 11s., and 21s. each.

Please note in connection with the recently observed effects of the use of Citrate and other preparations of Magnesia that **LAMPLOUGH'S PYRETIC SALINE** is warranted not to contain any substance, which would cause calculous or other earthy deposits.

H. LAMPLOUGH, 113, HOLBORN HILL, LONDON, E.C.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah in particular varies so much in the different provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

All correspondence must bear the full name and address of the writer, not necessarily for publication, but as a guarantee of good faith. We shall take no notice of anonymous letters.

CORRESPONDENCE.

THE ERGOT IN BARLEY.

TO THE EDITOR.

SIR,—The natives residing in a number of villages situated in the north of Perganna Imadpore of the Agra district, have

been suffering this season from the most frightful sores that can be imagined. Large malignant ulcers, in which, if granulation does set in, it is of a morbid character, building above the level of the skin an exuberance that gives the sores a fungoid, poisonous appearance. It is said to appear first in the form of a pimple, and I have remarked on some portion of the leg below the knee, generally midway, or if anything rather nearer the ankle, almost invariably on the outside. The pimple if abraded forms a sore which spreads rapidly and appears to know no limit; the smallest I have seen was about an inch broad and two inches in length, boat-shaped, and situated across the leg; and the largest about five inches by three, though I am told that numerous cases are to be seen in which the whole leg is involved. I have not heard of a single cure as yet.

The disease in this epidemic form first made its appearance about the time the wheat and barley crops were being harvested, and among the poorest portion of the villagers, which gave rise among them to the most absurd explanation of its cause conceivable. The E. I. Railway line which passes through these villages is being ballasted with broken sand-stone, which gets so hot from the heat of the sun as to blister the legs of the labourers. Most of the poor people in the villages being employed on the work, and the sores often originating from these blisters, gave rise to the idea that this was the source.

The malignant and epidemic character of the disease left not the slightest doubt in my mind that it was the result of blood-poisoning of some sort, and the casual remark of a cultivator to the effect that there had been a great deal of ergot in the barley and blight in the wheat this season suggested the probable cause of the epidemic. It is well-known that the continued use of ergot as an article of food has the effect of producing what is known as "gangrenous ergotism," and other malignant diseases appearing in an epidemic form. Epidemics of this nature have been recorded to have on many occasions affected whole districts on the Continent; and I strongly suspect that the use of ergot of barley will be found to be the cause of the trouble I speak of. The kind of ergot in question is called *kandid* in the vernacular, obviously derived from the word *kandā*, a cow-pat, a small fragment of which fuel it resembles closely both in colour and consistency. To give you an idea of how plentiful it is this season, I send you by to-day's post for inspection a handful of it which a man collected for me from his store of barley in a few minutes. I have no doubt that maunds could be collected if necessary. Unfortunately all the barley has been threshed or rather trodden out, and I was unable to secure a perfect ear. The present specimens are only fragments, and it is a wonder, considering their texture, that they were not entirely dissipated under the heavy tread of the oxen.

In the case of the official ergot of rye, each grain forms a separate ergot, whereas in the present disease all the grains are agglutinated into a mass which is covered with a continuous epidermis, very thin and shiny, presenting this appearance both in the fresh and dry state; fragments of this skin will be found adhering to some of the larger pieces of ergots sent. The place where the grain should be is marked by heart-shaped protuberances. The natives are unable to account for its increase this year, and believe, or rather say that they do, that a woman or child passing a field while it is being sown, with their eyelids blackened with *kajal* (lamp-black) will cause this blight. One old cultivator very gravely told me that this was nonsense and not to be credited, and that the true cause of *kanchea* was ploughing with a share the very day that it had returned from the blacksmith covered with black oxide.

I have been trying to recall all unusual circumstances of the past season:—We had a very severe frost that destroyed quite half the winter crop, and did some damage to the wheat, lighten-

ing the produce considerably; but this was after the grain had formed, and the ears are affected with ergot before this. But then again in the rains before this, there was a great blight of *judr* which was attacked by a grub; and to make up for the loss, hundreds of acres that would otherwise have been allowed to lie fallow, were sown with barley and sometimes wheat crops the ground had borne the previous season. This leaves room for speculation.

It is well-known that soil impregnated with the sporules of this fungous parasite will produce the disease in plants grown in it, if of the class the parasite attacks. More or less *kandua* is to be found in wheat and barley fields every year, and myriads of sporules must be scattered on them before the crops are reaped. Is it possible that the time required for a proper rotation of crops, and consequent delay of perhaps two years before the appearance of the particular crops affected by the fungus is sufficient to destroy the sporules, whereas a twelve-month is not? The greater number of the "*do fasli*" fields I have spoken about were sown with barley, being a more productive crop in poor soil than wheat; and, strange to say, it is this grain in which *kandua* is most plentiful. It is, unfortunately for them, the staple among cultivators. I sent for half-a-pound of mixed grain from the house of one of the sufferers, and though it was said to have been cleaned by his wife and ready for the hand-mill, had no difficulty in picking out small pieces of ergot, and by dusting the grain on a piece of white paper also ascertained that it was also mixed with it in a very fine powder.

The fact of the sores appearing very largely among labourers is probably due to the poor fellows being obliged to purchase flour from the *banya*, who, we may depend upon it, never bothers himself about picking the grain at all.

Wheat is, as I have mentioned, also attacked by *kandua*, but not so largely this season as barley. I send you, however, a few grains of blighted wheat, affected by the disease, also very prevalent this season, called by the natives (with a nasal pronunciation) *schūr*—I am sorry I cannot suggest an English name.

The ear of wheat affected appears quite perfect, or if anything, rather larger than the average of the field, but contains these abortive little black grains I send you, the most peculiar feature of which, and the one by which they are readily distinguished by the natives, is the division of the top of each grain into two little points. The natives do not believe them to be poisonous, but the sickening, unpleasant taste which even one leaves if crushed between the teeth and allowed to remain in the mouth for a little while, leaves no doubt that they are mistaken, as ergot of rye is described to have just such a taste.

To conclude, if some medical gentleman would suggest an inexpensive remedy and *regime* for the sufferers I have spoken of, it would be an act of charity. It is useless to tell the majority of them to go to hospital; they are too timid, and appear to me to prefer death. I have recommended purgatives, cleanliness, linseed meal poultices, and careful picking and washing of grain before grinding.

W. C.

Court of Wards, N.-W. P.

NOTE.—The samples of wheat and barley sent by our correspondent may be seen at our office by any one interested. We should esteem it a favour, if correspondents in other districts of India will kindly take the trouble to acquaint us with disease of a similar nature affecting crops.—*Ed., I. A.*

TEAK IN THE CENTRAL PROVINCES.

TO THE EDITOR.

SIR,—I have read with some surprise a notice in your issue of the 2nd July, concerning the supply of Teak available in the forests of the Central Provinces, and the necessity for introducing stringent regulations for the prevention of premature felling in those provinces.

I would ask you to give similar publicity to the following few remarks, with a view to correcting certain inaccuracies in those you have already published.

Your correspondent appears to be unaware that since 1867, no teak has been permitted to be cut except by feudatories and zemindars within the limits of their territories, without the permission of the district officer or his forest officer that the only large teak imported of late years into the

Nagpore and Kamthi markets is the outcome of the Panataras somindari, and that its price has been from Rs. 2 to Rs. 3 per cubic foot, and not 8 to 12 annas, as stated in your issue; lastly, the statement that the Alapilli forests had been ruthlessly cut into for the supply of sleepers for the Nagpore state line. As a forest officer, who has watched the Alapilli forests for many years, I would beg most emphatically to deny that they have been damaged by cutting for this purpose. These forests have been most anxiously studied by various forest officers, including the past and present Conservators of Forests of the provinces, and the past and present Inspectors-General of Forests to the Government of India. Not more than 20 teak trees have been cut since 1875 in the Government forests. Selection felling of *Saj* (*Terminalia tomentosa*) have been most carefully carried out, and yielded a lakh and-a-half of the sleepers required.

MADRAS.

NOTE.—The remarks of our correspondent to which MADRAS takes exception were received by us as trustworthy, and accepted, as many communications of a like nature must be, on the good faith of the writer. Our correspondent will probably have something to say by-and-bye. In the meantime we are anxious to give the fullest publicity to MADRAS's letter. Our regret frequently is that the pages of the *Agriculturist* are not more frequently taken advantage of to ventilate ideas on all the subjects embraced in our journal.—*Ed., I. A.*

THE INFLUENCE OF SUNHEAT ON THE SOIL AND PLANTS.

(To the Editor of the Ceylon Observer.)

SIR,—Mr. G. F. Walker and those who hold his convictions may be interested in the following extracts. I am with him in agreeing that we have been suffering from a want of sun-power of late years; and that it is not rainfall we have suffered from, but the long continuance of it with little or no intermission, and the absence of the requisite sunheat.

The sun of course is a most necessary factor in the consideration of climatic influence on vegetation; and no doubt the reason why (as some one remarked) one estate bears, while another does not, may in a measure arise from the power of retention or non-retention of the soil of excess of moisture. It takes a congenial season to make a healthy blossom!

The extracts are as follows:—"It has been calculated by Mr. Raikes, that the temperature of the soil, when drained, averages 10° higher than it does when undrained; and this is not surprising when we find that 1 lb. of water evaporated from 1,000 lb. of soil will depress the whole by 10°, owing to the latent heat which it absorbs in its conversion into vapour."

"Faraday calculated that the average amount of heat radiated in a day from the sun on each acre of earth in the latitude of London is equivalent to that which would be produced from the combustion of 13,000 lbs. of coal."

"Slightly beneath the surface of the soil in tropics, Humboldt states temperatures of 162° and 134° are frequently noted, and in white sand at Orinoco 140°, whilst at the Cape of Good Hope under the soil of a bulb garden a temperature of 150°, is recorded by Herschell. In China the temperature of water of the fields was found to be by Meyer 118°, and adjacent sand much hotter. These extremes of temperature would cause the specific gravity of the air to vary from 1.167 to 863 may serve as a kind of measure of the disturbing causes which interfere with the velocity and local direction of atmospheric currents and other phenomena, the calculation of which has been founded on mean results."

It would be a good thing if certain stations were with sunshine recorders, but perhaps their cost would be against their institution. Earth thermometers however are moderate in price, and are made to go as deep as 120 inches. There can be no doubt that the temperature of the ground greatly affects that which is growing on or in it.—Yours faithfully,

J. V. H. OWEN.

The Indian Agriculturist.

CALCUTTA, AUGUST 1, 1883.

THE PIONEER AND THE INDIAN AGRICULTURIST.

OUR Allahabad contemporary says that it is "perplexed with doubts as to the trustworthiness of the *Indian Agriculturist* on a subject so well within its province as manure." The *Pioneer* is modest enough to admit that these doubts do not arise from a more intimate acquaintance with Indian agriculture than is enjoyed by the *Indian Agriculturist*. This perplexity, on the part of our contemporary, has arisen, it seems, from "some very positive assertions," recently made by the *Indian Agriculturist*, and the conclusions arrived at by Dr. Voelcker in a late number of the Journal of the Royal Agricultural Society. The *Pioneer's* perplexity of doubts seems to us to arise from the confounding as identical two things, which are totally different. These are—*first*, the value of nitrogenous manures; and *second*, the validity of the conclusions drawn by Mr. Fuller from experiments made on the Cawnpore Experimental Farm. We need scarcely say that we have never at any time under-estimated the value of nitrogenous manures. Our ideas regarding manures in general and their classification may, we think, be fairly gathered from several articles which appeared in this journal in the year 1879, and one of which the Government deemed of sufficient value to reproduce in the *Gazette*. To have a due appreciation of the value of manure is one thing; to question the sweeping conclusions drawn from a few experiments is another, and a totally different thing. The *Pioneer's* perplexity appears to us to consist in crediting us with unbelief in the efficacy of ammoniacal manures, when we really neither hold nor express such unbelief, but in reality venture to withhold our assent to conclusions which seem to us to be based on an insufficient substratum of experiment. It would not be difficult to show that we are not alone in believing that the deductions made from the Cawnpore experiments cannot be accepted without considerable limitation. We venture to reproduce the following extract of a letter which appeared in our columns on March 1st, 1883. The writer is Mr. O. A. Hill, B.Sc., F.C.S., Associate of the Royal School of Mines:—

"Mr. Fuller has committed the mistake in inductive logic of basing a wide generalization upon a very limited breadth of experience. His remarks may be understood to imply that in all Indian soils, and for all crops, nitrogenous manures are the most valuable; whereas, all that may be legitimately inferred from his admirably conducted experiments, is that on the experimental plots of the Cawnpore farm, in their present condition, the manure most required for a wheat crop is a nitrogenous one—the manure most required for a different crop on the same ground, or for wheat in another part of India, might be a very different one."

No one, we suppose nowadays, who knows anything of the science of agriculture, would venture to assert that nitrogen, and nitrogen alone, is all that is required in the matter of manure to render every field fertile and every crop a bumper. Some such belief did certainly prevail thirty or more years ago, but, as we ventured to say, the craze for nitrogenous manures died away when their true relative value came to be understood. In reviewing the Cawnpore Farm Experiments, 1881-82, we said: "Comparative experiments have everywhere proved that the use of any one fertiliser, whether nitrogen in any of its forms, or lime, potash, phosphoric acid, or ~~any~~, has always produced conflicting results, indicating, as a disturbing cause, the presence, in different proportions in the fields experimented upon, of some available plant-constituent or constituents which the fertiliser assisted the plants in absorbing. It follows that the repeated use of a given fertiliser (as proposed for nitrogen by the Assistant Director of Agriculture) must progressively impoverish the soil of the co-active

constituents sooner or later, and reduce the outturn of the crops to nothing. Mr. Fuller's experiments have not embraced this feature of the case, or he would not have over-rated nitrogen, essential though it is to plant economy. That no one plant-constituent is of any value in the soil by itself, and that several contribute to make up a plant, is a cardinal axiom that should never be lost sight of. The Cawnpore experiments conclusively establish this. An *unmanured* soil (page 288 of the *Government Gazette*, already quoted) yielded 771lbs. of wheat per acre. The same soil, fertilised with nitrate of potash at 240lbs. to the acre, yielded 1,605lbs. Difference in produce—834lbs. Another *unmanured* soil yielded 777lbs. per acre, and when similarly nitrated, produced 1,242lbs.—difference in yield, 465lbs. If nitrogen is all that Indian soils need, explanation of the disparity in yield of the nitrated plots is necessary. The two *unmanured* soils, it is worthy of note, were in the present instance in identical conditions for experiment. There was a difference of only 6lbs. per acre in their *unmanured* yield; yet, when nitrated, one field yielded 369lbs. per acre more than the other! There is but one explanation of this. One field had more assimilable plant-constituents awaiting excitation with activity by nitrogen than the other; and the conclusion that follows is, that *something besides nitrogen* is needed for Indian soil."

We trust we have, so far made our position sufficiently clear with regard to the criticism which we ventured to make on the conclusions arrived at from the Cawnpore Experiments. In replying to a leader in the *Pioneer* (we think), which was based on the January articles of the *Indian Agriculturist*, Mr. Fuller in a letter to the *Pioneer* shielded himself behind the authority of M. G. Ville. We have not his letter before us, and write from memory only; but so far as we recollect, he affirmed that his experiments were carried out on the lines marked out by M. Ville, whose work he very properly stated had been crowned with all the honours which scientific societies could confer on them. M. Ville's work was published in 1879, and translated and edited by Mr. Crookes, F.R.S. In the pages of the *Agricultural Gazette* for January 1883, Sir J. B. Lawes subjects M. Ville's statements to a destructive criticism, from which it is very doubtful whether the reputation of M. Ville will ever recover. We do not blame Mr. Fuller for bringing to his support all the authorities he can muster, but in the instance quoted he has been unfortunate. In closing a long article dealing with the series of articles written by Sir J. B. Lawes for the *Agricultural Gazette*, the *Field* says:—"As regards the important question as to the sources of the nitrogen of plants, M. Ville's statements as to the power of plants to derive a portion of their supplies directly from the air is blown to the winds by a mass of facts, the result of actual experiments. M. Ville states that nitrogen is assimilated by plants in three different forms, viz., as ammonia, as the nitrate of some base, and as nitrogen gas; and that it has been ascertained that 'crops always contain more nitrogen than the manures supplied to them, and this excess is derived not from the soil, but from the air.' Such a positive statement is proved by Sir J. B. Lawes to be absolutely erroneous in every instance. Wheat most nearly, of all our cultivated crops, accounts for the nitrogen supplied in manure. In every other instance where excess of nitrogen above that contained in the manure is said to be derived from the atmosphere, the very opposite is the fact—the manure contains more nitrogen than appears in the crop, and a considerable loss occurs. In the analysis of the soil in which his experiments were carried out, though made with the greatest care, no mention is made of nitrogen, but he refers to it as similar to that of Rothamsted as to the nitrogenous matter. Sir J. B. Lawes states that within reach of agricultural crops, the arable soil contains from 10,000lbs. to 12,000lbs. of nitrogen per acre, but apparently M. Ville leaves this out of calculation altogether; and, because he finds more nitrogen in certain crops than was applied in the manure, jumps to the conclusion that the balance was derived directly from the air. In the case of wheat—which, as has been shown, makes the best use of the nitrogen supplied—it is shown by the reviewer that 1 cwt. nitrate of soda furnishes 17lbs. or 18lbs. of nitrogen, and that if every particle were taken up this would suffice for 11 bushels

of extra wheat, and he thinks farmers would be satisfied with 6 bushels on an average, and that even in 1863, the year of maximum produce at Rothamsted, the amount of nitrogen in the increase of the experimental crop was considerably less than that supplied in the manure. * * *

Sir J. B. Lawes points out many other errors which our limits will not allow us to recognise. Enough has been advanced to act as a warning to our readers not to blindly follow the advice of one who, however well-intentioned, is not a farmer, nor a scientific man, but who is evidently profoundly ignorant of agricultural practice."

Mr. Fuller has mentioned M. Ville as the man in whose footsteps he has followed, and now the *Pioneer* brings forward Dr. Voelcker as the eminent authority who "bears out with extraordinary force the results of the Cawnpore experiments."

The *Pioneer* will probably be surprised to learn that the experiments of Dr. Voelcker which it brings forward in confirmation of the Cawnpore experiments not only reveal nothing new which was not established beyond all possibility of doubt many years ago, but are merely confirmations of an earlier experiment. Sir J. B. Lawes, then Mr. Lawes, more than thirty years ago conducted the following experiment:—

Two plots of land, side by side, for eighteen years were manured alternately with ammonia salts and phosphate of lime. In 1852, plot No. 1 was treated with ammonia, plot No. 2 received superphosphate. In 1853, No. 1 got superphosphate, and No. 2 ammonia; and so on for eighteen years. Thus, each plot had been nine times manured with ammonia and nine times with mineral phosphates. Over the whole time the average produce of both was exactly the same, 24½ bushels; but the average of the eighteen crops grown by mineral manure alone, whether on plots No. 1 or No. 2 was only 17½ bushels; whilst the average of the eighteen crops grown on either plot by ammonia salts was 31½ bushels, being an increase of nearly 14 bushels per acre more each year. These results, confirmed by Voelcker, and tested by the practice of agriculturists, were accepted among scientific agriculturists long before Mr. Fuller's interesting experiments in the same direction were thought of. The *Pioneer* will probably now understand why we could see nothing astonishing in the Cawnpore Experimental Farm experiments, and why we do not feel at all annihilated by Dr. Voelcker's paper in the *Journal of the Royal Agricultural Society*. Dr. Voelcker is but following in the footsteps of Lawes, and the latter left nothing to be performed by those who came after him but confirm what he had established.

The chief source, however, of the *Pioneer's* perplexity arises from the "grave discrepancies between some very positive assertions recently made in the *Indian Agriculturist*, and the conclusions arrived at by Dr. Voelcker . . . which bear out with extraordinary force the results of the Cawnpore Farm experiments and the conclusions which we drew from them," and the writer in the *Pioneer* "doubts whether the *Indian Agriculturist* will find it worth while to quarrel with so high an authority as Dr. Voelcker." Here, again, it seems to us there is confusion of thought, and a consequent inability to grasp the points at issue. So far as we are aware, no one doubts that both at Cawnpore and Woburn, the yield of wheat from nitrogenous manures was very marked. Had Dr. Voelcker, however, gone on, as Mr. Fuller has done for India, to draw from the Woburn experiments the conclusion that it is nitrogen alone that is deficient in the soil of England, not only would the *Indian Agriculturist* have "quarrelled with so high an authority," but every scientific agriculturist in England would have laughed in the doctor's face.

We may be permitted here to say a few words anent the criticism which the *Pioneer* recently made on an article of ours regarding the appointment of Major Pitcher. In our June number, we said, "We have no knowledge whatever of Major Pitcher. He may be the most suitable man in all India for the position he has been placed in at Cawnpore; but this square-mayground-hole business of placing soldiers and warrior judges, in charge of Experimental Farms, seems to us about as wise as placing ploughmen and pig-drivers in command of regiments, and giving district and divisional commands to growers of big cabbages, superlative turnips, and gigantic gooseberries."

The *Pioneer* was then good enough to vouch for the superlative fitness of Major Pitcher. He had specially studied agriculture during a recent furlough to England, and was out of sight the best man in the province for the position. Will the *Pioneer* inform us if there is any country in the world besides India where the servants of the State are asked to perform such widely differing duties, demanding special knowledge, as that implied in the translation of a Small Cause Court Judge to the practical control of a scientific Experimental Farm? So far as we are aware, the control of Experimental Farms is given in England and the Colonies, Germany, France, America, and elsewhere, to men who have made a life's study of the subject, or who have been specially trained for the purpose. In India, a clever civilian or a clever military man is deemed able to cope with anything—from the demarkation of a ryot's holding to the government of a province, and the idea never seems to dawn on those who make such amazing appointments, that the purposes of the State would be better served by importing men from England— young men who have studied agriculture in theory and practice in the best schools of Europe and America. The Bengal Government is about to establish an Experimental Farm. Will there in this case also be a clever civilian appointed, or will the Bengal Government look for a man of ripe experience who will redeem Indian Experimental Farm reports from a good deal of twaddle?

The *Pioneer* has been good enough on several occasions in recent years to criticise and lecture the *Indian Agriculturist*. May we take the present opportunity of returning the *Pioneer's* compliments? We strongly advise our contemporary to write about subjects which it understands, and leave to journals such as the *Indian Agriculturist* the discussion of technical topics which lie outside the rim not only of the *Pioneer's* knowledge, but which apparently stand beyond even the circumference of its conceptions.

NOTE ON THE CAUSES RETARDING IMPROVEMENT IN CATTLE-BREEDING AMONG CULTIVATORS OF THE HINDU CLASS IN THE DOAB TRACT, ABOUT THE VICINITY OF DISTRICT ETAH, N.-W. P.

THERE appears to be a great deal of something not quite comprehensible in connection with cattle-breeding among Hindoo cultivators about this part of the country; not speaking of professional breeders, but of the great mass of agricultural people. The male of the cow species furnishes the draught server in agriculture, and the female of the buffalo species the milk supply; the opposite sexes on either side being comparatively useless except for propagation, and it would seem reasonable that before a proper means could be devised for improving either or both of these species, that we should form, if possible, a correct appreciation of the causes and of the effect, whether detrimental or otherwise, of these exclusions on the general conditions of the animals.

A cultivator in these densely cultivated districts, if asked why he does not keep a greater number of cows and breed his own draught cattle, invariably answers that it is because he has no grazing grounds. Reflecting no further than that this is a fact, many have been led to the conclusion that there is some inherent infirmity in the constitution of the cow that renders it impossible for her to exist without grazing on a pasture, this not being the case with the buffalo. The buffalo in the matter of grazing has, if anything, the advantage over the cow of habitually grazing at night, and of grazing in a pouring rain, and perhaps of protecting itself from flies, a serious obstacle to grazing, by covering itself with a coating of mud. Whether these advantages are admissible as such or not does not alter the fact—that there are no perceptible physiological reasons why the cow should need to graze and not the buffalo. That the cultivator will keep buffalo cows but not cows unless he has pasturage for them, is a fact, but some other reason must be assigned for it, the most plausible being that as stall-feeding is much more expensive than grazing, it does not pay to stall-feed cows.

The first fact that is always thrown in your teeth, by cultivators of these parts when urged to increase their stock of cows is, that the buffalo averages a supply of three times as much milk as the cow—8 seers against her three; but as it is well known that the milking qualities can be bred and improved, that English cows, when properly fed give an average of 12 quarts—quite 12 seers, and that many country cows have been, and can be brought to give the same, the inference is that she is neglected. Large milk-giving capacity is obviously as much an artificial condition in the cow as the length of forearm and other peculiar physical conformations that give the English race-horse the speed he shows. The great development of udder and lean condition that characterizes the first-class milch-cow in working trim is a form obviously quite unsuited to any animal in a wild state, dependent chiefly on speed for its preservation as most of the herbivora are, and judging from this, any approximation to this state must be a retrogression from good milking qualities. Allowing cattle to graze in large herds with the object of securing bull calves which are allowed to suck their dams as often as nature prompts is, it is to be feared, an approximation to the wild state, and most of the breeding in India is done in this way.

An interesting enquiry now remains, which is—why it is that the she-buffalo has supplanted the common cow in the dairy of the Doab Hindoo cultivator? Supplanted she has been. Setting aside other weighty reasons, it is traditional that the general use of the milch-buffalo is comparatively recent, and it is well known to be extending. However unexpected the conclusion may be, it is strongly suspected that the veneration in which she is held by Hindoos has had a great deal to do with bringing about her degeneration. The first objection to keeping a cow by Hindoos may have been the fear of her getting into the clutches of beef-eating people when these people ruled the land; and it will not be surprising if the first impulse to buffalo-breeding proves to have been given during the time of the Mahomedan conquests. This, in the absence of proof to the contrary, hardly admits of doubt. To this day, despite the relaxation in Hindoo religious discipline, it is deemed a disreputable act to sell a cow at all, and decidedly improper and sinful to sell her to people likely to devour her, or desecrate her sacred person in any way, and we can readily imagine how glad the conquered Hindoo must have been to find a substitute in the buffalo, regarding which animal there are no such scruples. There can be no doubt that foraging parties from large Mahomedan armies secured their beef by force, it being highly improbable that till a very late period they could have purchased enough for their wants with Hindooism at its height; to say nothing of their early policy, which was by no means one of even religious toleration.

2. The very important question of gelding to which no one appears to have laid much weight.—No Hindoo about these parts would dream of emasculating an ox; even a *chamar*, in this part of the country at all events, would be instantly outcasted did he attempt it, for we know of an instance where this was actually done, though the man kept up the trade in spite of the disgrace. But at the same time, no cultivator would care to yoke one that had not been so treated; besides the docility and lessened liability to constitutional waste secured, there is a tacit conviction, only very occasionally expressed, that the unsexed beast has lost its sanctity, and that whatever objection there is to working the entire bull, there is none in harassing the unfortunate "*budiyas*," as the geld animal is called. Can we conceive anything more deleterious to cattle-breeding and disadvantageous to agriculturists than this objection to castrating? The ordinary cultivator now, unless he wishes to release a "*Brahminy Bull*" after the death of a relative, is bound to sell his bull calves, and under most disadvantageous conditions for he must have *budiyas*. The few that do use entire bulls, nevertheless bred by themselves, make a great merit of it as manifesting their devotion to their religion, and carefully fix a plank across the horns. You are occasionally told that So-and-so owns a bull as docile as a geld ox; but these exceptions only prove the rule, and the sad truth is that the majority get more dreadfully vicious, and are sold to the "*Banjara dealers*" for a mere song, if not presented to them, on condition that they will catch the beasts themselves. A party of Banjaras were observed a few

days ago near the tehsil town of Itmadpore in the Agra District, driving away a number of mature bulls that they had evidently purchased from cultivators who had kept them entire in the hope that they would prove docile. The poor beasts had been subjected to the excessively cruel process of castration, known as "*crushing*," and were being forced to march before the inflammation, which is always very great in this process, had subsided. "*Incision*" does not appear to suit mature bulls, and the small liability to tetanus displayed in the bovine species allows of the crushing process being carried on with impunity; in the horse, it frequently results in tetanus. It was probably the intention of these men to dispose of the animals in large cities for heavy cart work, as late castration never ensures a perfect temper. The operation of gelding is always performed by the first year in the case of cattle required for light, active work, as most well-bred animals are; it lightens the neck and shoulders. The heavy neck being a sexual sign is only acquired at maturity, and it is only cattle that are required for heavy, plodding work, that are allowed to acquire something of this form before being castrated. After the second year and before the third, must be the time in this case. Both well and plough work are best performed by active animals, and cultivators, when wishing to praise their cattle tell you, that they "*actually jump down the bullock-rim*" or "*fly with the plough*." The value of a bull-calf decreases every day after the proper time for castration has expired, and the shortness of this period, combined with the absence of a competitive mart, leaves very little hope of a good bargain being made by the Hindoo cultivator.

This objection to rendering the animals serviceable, on which they are dependent for so much, can only be regarded as a great social evil among these people. Everybody knows that you must have gelded oxen, that the bulk of the animals must be purchased from Hindoos, yet they refuse to geld, and there must be no ostentatious sale and a large seasoning of sophistication even with the ungelt animals. Your respectable Hindoo should not go dancing about a mart—who will buy?—with his cows and calves; they should be sold at home, if at all, with pretence of the sale being really a gift, and a respectable native will often tell you with pride that a cow has never been sold from the stalls of his family within the memory of man; you may sell to the *chamar* and he to the gelders if he is not over-anxious about his soul; then you may buy "*budiyas*," but not the particular ones bred by you. This would be indecent, and you would be throwing yourself open to suspicion. Your brother may buy such animals but it is considered an uncanny thing to do. The *banjara* who castrates is the customer; he is oftener a Hindoo than a Mahomedan, and it is pleasant to deceive yourself with the reflection that you sell to a Hindoo. This, almost the only, legal customer belonging to a vast clique, can demand his own price for entire bull-calves. They are now with the cultivator of such a wretched breed that he scarcely offers anything for them: Rs. 10 is about the average. The *banjara* gets his stock from breeders in well known districts, but if a cultivator purchasing draught cattle from him, happens to have a male calf, it is sure to be thrown into the bargain at a dead loss. Bound to be of a vile breed, it is, after castration, sold to some unfortunate *chamar*. Taking all this into consideration, it does not appear astonishing that a cultivator should show no anxiety to improve his own breed, and that he should neglect the splendid opportunities offered him by Government of well-bred bulls. One would think that the best inducement to general improvement would be the guarantee, if possible to private breeders of a fair price for their entire bull-calves of a certain standard. Perhaps it would then pay to stall-feed cows of better quality, and the objection of "*want of pasturage*" would not be raised so frequently.

The writer knows of an instance in which a beautiful black Hissar bull, one of a number furnished by the Awah Estate under the Court of Wards, was scarcely tolerated for the first few months of his being stationed and advertised free of charge for the use of all cows brought to him, and is now flocked to by cultivators, it is confidently believed, because the Agricultural Department have begun to give prizes for cattle at fairs. The bull has been about 20 months at one depot, and is now the sire of 73 beautiful calves, 57 of them males and more

peculiar still, all black like him. The owners of a few of them being told that they could compete for prizes at the Batear fair appeared pleased, but remained quiet, it is suspected, because they are poor men, and weigh the chances of taking a prize against the expense of travelling, to say nothing of neglecting their *rabi* crops, as the fair takes place in November, their being no reasonable hope of their selling the entire calves to advantage. They were asked what they thought of selling their calves, with two teeth, to Government for artillery purposes, and, of course expressed their approval and opinion that it would pay to visit the fair under these circumstances. The Government demand for oxen for military purposes is very large, and there should be no difficulty in giving a guarantee for the demand, particularly when a very superior standard could be fixed. They could be purchased entire at about 2½ years, and castrated. The late gelding would leave their necks rather heavy, but perhaps this is just the form wanted, for the heavy draught work they are put to. There can be no doubt that this would throw a fair share of the trade into the hands of cultivators, in whose interest we write, and by making them regular cattle-dealers, perhaps eventually induce them to throw aside scruples about castration. After all, the objection is very weak and unsound in a religious point of view. A brahmin was asked to explain how, if castration was so sinful, he reconciled himself to purchasing gelt cattle, his moral responsibility as purchaser being just as great as if he had performed the operation himself, inasmuch as if he did not make the demand, it would not be the interest of dealers to geld. He could only answer that it was not the practice, and added that there were some otherwise orthodox Hindoos who went so far as to sell their calves to castrators, and then purchase them back for a slightly larger sum, really the gelding fee, but that they only did it because it has been the practice in their families for ages. The best cattle for general use about this district are brought from the Mearut country. The Merati is a Mahomedan, and has no scruples about castrating. The Jat also, unless living among scrupulous people, is not very particular in this matter, and breeds good cattle. There is reason to be afraid that no breeder could make the business pay if he objected to geld his own stock unless specially supported.

3. *Food*.—In the case of a buffalo-cow every particle of waste food and leavings in a Hindoo household can be utilized, but not so with the cow: it would not be proper to feed her on leavings of food—*jhuta*. The imperfect digestion of the horse in comparison to that of ruminants, allows of the dung of the former being given freely to the buffalo with the effect of fattening and increasing milk: the only objection being, the horse odour, which can be detected in the milk. Low-caste natives do not hesitate to feed their cows on it as well, and it is apparently not considered as objectionable as *jhuta*. The few people, well-to-do cultivators, respectable Kaiths, &c., that do keep a cow or two, the smaller the better as they will eat less, say that they only do it so as to be able to perform certain religious ceremonies with facility, and that if it were only a matter of milk it would only be more profitable to keep a goat. The object is to salute the beast, and look at her face the first thing in the morning. Give her a little of their food before eating themselves, (a meritorious act) secure "products" for the purification of their hearths, &c.

The buffalo is said to have the superior advantage of being able to eat certain cheap fodders that the cow will not; we know of none in daily use. The cow does not refuse castor, neem, babul and jharberi—the four extraordinary fodders used about here. We do not do natives sufficient justice when we imagine that they cannot calculate on the niceties of agricultural economy. The following is what a shrewd Kaith, who by the way owns a cow, told us: "there is one little advantage that the keeping of a cow should be credited with. If in grazing about it enter a field of corn, there is a chance of the cultivator saying, 'It is a cow, let it eat,' but heaven protect the buffalo detected at any similar little game."

On the whole, I should not think that the buffalo has any very superior advantages under this head; perhaps what is meant is, that coarse food gives more profitable results in the case of the buffalo than it does in that of the cow, in the matter of milk.

4. The buffalo is said to last longer than the cow, and a common native proverb is,—

Gai durā dhōrī, bhains tērā dhōrī. This, when literally translated, means—that while the cow is aging after her second calf, the buffalo is scarcely affected by her third calf. Of course, the numbers here are exaggerations but it shows the prevailing impression. It is understood to be an established fact that the better fed an animal is the more virility will it show, and if the unfortunate cow is to depend upon "usar" pastures for its support, the origin of the proverb is not long to be sought for.

5. There are religious objections to selling a cow, but none whatever to selling a buffalo, and one can understand a poor but pious Hindoo cultivator who knows that he may be forced to sell his milch beast any time, selecting the buffalo.

6. A buffalo proving barren does not throw a cultivator so completely off his centre if we may use the expression, as in the case of a cow, the latter would prove a burden as it would not be easy to get rid of her while the former can and will certainly be put to the plough or yoked to the well rope. From the superior attention paid to her, she shows more bulk and bone than the average male buffalo, and makes a very fair draught animal. A short time ago we came across a cultivator working a barren cow-buffalo, at a well; it appears that he had worked her for 6 years. He originally trained her, influenced by the idea prevailing in these parts that work sometimes removes sterility. As she did not improve but worked very well, he continued working her. The usual thing is to make the barren cow-buffalo over to the carrier who loads and works her freely returning her when she shows signs of recovery, if she ever does. A large proportion of the buffaloes that may be seen carrying grain to the Agra market of a morning, will be found to be barren females.

7. If a Hindoo kills a buffalo accidentally, it does not matter in the least as it does in the case of the cow, when he has to perform penance of no ordinary severity. In fact, he compromises himself rather seriously if he allows her to die with a rope round her neck, and tethers are carefully removed from cows believed to be dying. Thakurs sacrifice a buffalo to the goddess *Kali* at the *Deshara* festival.

8. The bull buffalo as a draught animal for agricultural purposes holds a very inferior rank, bad for well work, for he is slow and cannot bear the heat of the sun. Bad for ploughing because he will not walk straight, and it is not easy to make a clean, straight furrow with a pair. What is generally done is to pair a buffalo and an ox: the ox keeps the buffalo straight, and they manage to get along pretty well. Even this is objected to very strongly in a proverb that we cannot do better than give—

Bhainsā bard ka khētī karā, karna kār birāno khāē, Badiya ainchat hāē bhūran ko, Bhainsā khench dehar ko jāē, aur jēkar ghar mē nar karkesā vo nar biṣā maūt mar jāē; Or—He that ploughs with a buffalo-bull and an ox will know (bitter) debt, for the ox will draw up towards the dry sand and the buffalo will drag down towards the swamp; and he that has a shrew for a wife will die before his time.

Of course only *chamars* and such low castes use them for ploughing and irrigating, though all classes use them for carts. We were once given, by a cultivator, a very lucid illustration of this tendency in the buffalo not to walk straight. He unyoked a pair of oxen, and they immediately started off unattended for a clump of trees where they were daily tethered and fed. He then unyoked a pair of buffaloes, and they as soon commenced straggling about in opposite directions as if unaware of the existence of the trees where they were also daily attended to, and had to be pushed and pushed into the proper direction. Perhaps, through the stupidity of the beast, it is not possible to train it so thoroughly as the ox.

Natives have a proverb to the effect that you should not count on your buffalo till the calf has weathered three winters, showing that the mortality among them till they arrive at maturity is considered great, but it must be the same with the male produce of all milch stock, particularly where they

are of scarcely any value. Buffalo-calves are said, however, to be very susceptible to cold. Nor can very young animals endure the hot wind and at this time of the year they are found to thrive best in an enclosed room the floor of which has been flooded and worked up into a puddle; the steaming atmosphere of such a place suiting their temperament. Male calves are hardly allowed enough food to keep them alive; it cannot be afforded when the milk which they require is more valuable than the calf itself. The latter sells for about 4 rupees when 18 months old, and the very butter-milk it would have required in this time to keep it in health is worth more, let alone the butter which the cultivator cannot afford to eat himself. In the bovine species the rule does not admit of exception that the male is naturally larger than the female, and the reverse being the case with the ordinary breed of buffaloes about here, the conclusion is that it is the result of unnatural starvation. Natives tell you that they cannot keep up a suitable breed without refreshing by importation of stock from localities where the animal thrives best. It is very likely that the neglect of the males of the home stock, already spoken of, partially accounts for this necessity, though we must not lose sight of climatic unsuitability, the natural habitat of the buffalo being a moist warm climate. A well-informed and experienced English gentleman who has resided in the part of the country between and about Agra and Delhi for more than 30 years, tells us that efforts were made in days gone by, to introduce the huge Bengal buffalo, but without success, and that the breed known as the "Sindhi" recognized by their great size and more especially by their twisted horns, which like that of a ram form quite a ring, have always proved superior and best suited to the locality. The famous milk buffaloes of the "gaddis" or Mahomedan milkmen of Aligarh are said to be of this breed. They have the reputation of being very careful about the breed of their cattle, and to be very chary about parting with good males bred for milk stock.

9. Buffalo milk is said by the natives to have a greater specific gravity than cows' milk, and to be in consequence more satisfying food, and at the same time to contain more butter; but then they tell you that the quantity of butter in the milk of a buffalo-cow, though averaging 6 per cent by weight, is as much subject to regulation as the produce of a field. Feeding on cotton-seed immediately increases the butter per seer of milk, though at the same time it reduces the quantity of milk, but the balance of profit is universally admitted to be on the side of cotton-seed feeding, if for no other reason than that it is easier to extract butter from rich milk, and the animal keeps in better condition. Natives here say that feeding on the grain called *wat* has the peculiar effect of producing an inordinate flow of milk in the buffalo that ruins her in a very short space of time, and that it is a favourite trick with dishonest people that wish to sell her to advantage. It is only suspected at present that if there is any difference between the specific gravity of the milk of the cow and buffalo, it is the result of difference in bulk, and that the same difference would be found between the milk of very large and very small cows. It is an open question. In short, one is led to believe that this advantage, if such it is possessed by the buffalo over the cow, is also the result of neglect and consequent degeneration in the latter.

There can be no doubt that investigation would elicit other points of difference between the two species that would show advantages and disadvantages in each; but those mentioned seem the most important, and would appear to justify the following conclusions:—

That the ordinary Hindoo cultivator finds it more to his advantage to keep milch buffaloes than milch cows. The reason for this does not appear to be because the cow is constitutionally unsuited to bear comparison with the buffalo in milking qualities, but because religious feelings brought about a neglect of the cow that resulted in her degeneration. That these feelings still influence the Hindoo, and have organized a condition of pecuniary loss in bull-breeding among cultivators which as the bull furnishes the draught power in agriculture, represents a needless loss in this industry. That unless things are remedied and the prospects of gain enhanced, the neglect will continue.

That the encouragement of a competitive demand under conditions that do not compromise the Hindoo with his society, accompanied with aid in the shape of well-bred sires, and if possible, a guaranteed demand for good steers,—in fact, means taken to ensure a profit to the breeder although he cannot command a cheap pasture for his stock, will, as in the case of horse-breeding, ensure the improvement of cattle among agriculturists, and throw a profitable industry into their hands, particularly if the cow can be brought to rear good bull-calves, and furnish as much milk as the buffalo at the same time.

That though the buffalo being an exotic animal is likely to die out very readily if the above end is obtained, she now holds the place of the milch beast admirably, and taking religious prejudices and all things into consideration, her improvement is worthy the consideration of those who would aid the ryot, the greater part of whose rent she now pays, her keep, as has been often pointed out, representing an annual profit of Rs. 40 to a cultivator of 10 acres of good land, who is enabled through her to utilise certain productions of his fields that would otherwise be wasted.

That nothing but the ordinary idea of supplying good animals for sires, and discouraging breeding from any others, appears to be wanted for the improvement of buffaloes, they being so much in vogue; unless a demand could be found for good males, indispensable animals for draught and burden in marshy districts.

W. C.

OUR WEATHER OFFICE.

A GOVERNMENT whose financial prosperity and very existence depend on direct income from the land, may appropriately subsidise science in the pursuit of weather-laws—these intimately affecting the prosperity of the agricultural masses. And it is well that the solution of a great problem has been undertaken in India as elsewhere by State resources, which alone can make success possible. For some years past the Government in this country have responded liberally to the ever-increasing demands of the Meteorological Department for expansion. The operations now extend over an area which must be the envy of European meteorologists, and the compactness of its administration is doubtless an element of efficiency. That it should seek to justify its existence in attempts to forecast the weather is commendable, while in conformity with natural expectation of the due exercise of the functions with which it has been presumably endowed.

Unfortunately, here, as elsewhere, the fluctuations of a column of mercury, representing variation in air-pressure or tension, have received undue prominence: and are held to comprise the secret of long-sought weather laws. Degrees of tension, however, have no known or recognisable sequence, and wanting this knowledge and much else, forecasts as now constituted must usually prove illusory. Occasional conformity between forecast and weather proves nothing—furnishes no weather law—for weather-casts, avowedly empirical, score as many successes as those emanating from highly organized State departments, equipped with costly appliances and invested with scientific *colat*.

The telegraph has been employed here, as in Europe and America, to announce the periodical and season weather changes, which, first manifesting themselves in known confines, extend over large and varying areas—but this operation scarcely comes within the domain of prediction. The area's intensity, and duration of weather-phases (the *ultima shule* of meteorology) are not details which the telegraph can determine. No forecast, for instance, of the probable duration, intensity, direction, and limit of the air-depressions, *alias* rain or monsoon currents, which appear at intervals on the Bengal and Bombay currents, and travel into the continent of India is possible by the telegraph. But such information accompanying the intimation of the appearance of the depressions would be valuable to the agriculturist. Of course, it would be still more valuable to be informed in advance by the weather office when and where these depressions would form, and the area they would affect. As with those monsoon depressions,

however, so with the American storms which are alleged to traverse the Atlantic. Not always do these reach England or France. They frequently end somewhere on the ocean. The weather office fails to give any information in this respect; it is helplessly confined to telegraphic intimation of storms having commenced in certain American localities, whence they are hypothetically held to cross the Atlantic to Europe. It is not by any means established that all Atlantic storms originate in America, or that any storm so originating has actually been traced to England and France. What is suggested by the knowledge obtained is a probable co-incidence at times between disturbances gradually extending over vast and varying areas. The practical worth of the weather office in Europe and America, as in India, in fact begins and ends with the telegraph which is not a meteorological instrument at all.

It is true that the weather office in England claims the fulfilment of 80 per cent of its predictions, but departmental statistics, departmentally interpreted, are not necessarily contributions to eternal verities. In India, for instance, the secretariat conclusions from jail and police statistics often conflict with departmental deductions, and tone down considerably departmental self-satisfaction. But any deduction, however authoritative and entitled to respect, must be vitiated if all the factors in a question have not been tabulated. Some years ago the head of the Medical department in England declared that departmental statistics proved the health of the Indian army to have been strikingly benefited by recently improved sanitation. The jubilation among the official constellations was however brief. An Assistant-Surgeon suggested that the diminution of mortality and sickness was rather the outcome of increased invaliding—a factor that had found no expression in head-quarter statistics.

The 80 per cent confirmations claimed by the weather office in England must be appraised by their character, as well as by the character of the 20 per cent failures. The last presumably comprise the unexpected incidence of great storms which inflict severe losses on the mercantile community. The department has not on the other hand been able to establish to the satisfaction of anybody but itself, any diminution of shipwrecks and consequent loss of life, or of any benefit to agriculture or to the population at large, through its alleged triumphs. No aid given by the telegraph in estimating the *direction*, for instance, of a storm already in incidence at a distance, is a meteorological prediction for the localities warned to prepare for it. Still less are pretensions to a prediction in such cases admissible when neither the duration nor distribution of intensity is notified. There is no basis to proceed upon in these respects. And when we bear in mind that in England weather phases, unlike those in India, are comparatively of brief duration, it is always likely that a prediction during a period of disturbance, of the cessation of that disturbance within a certain number of hours, will be verified—even when not scientifically based—and the same for deductions as to duration of calms according to season. The bulk of the 80 per cent verifications consist of such triumphs, the scientific premises in which are more or less contestable, while the conclusions are endorsed, as it were, by a cynicism of nature. The public estimate is adjusted accordingly. Again—the alarm through hoisting of cones and other signals on erroneous deductions from telegraphic and other data, makes the community eventually distrustful or indifferent to warnings unless confirmed by local weather knowledge assisted or not by instruments. This is very natural; for the loss of time which means loss of money in a commercial and maritime country through concessions to miscalled science, must ultimately create contempt of efforts, however scientific the alleged basis.

On a par with the above, but on a vague and still less tangible basis are the speculations by our Indian weather office on the character of an approaching "rains." To predict for instance, an average, or more or less than average "rains," conveys no information of any value to the almost purely agricultural population, while confirmation can scarcely suggest a scientific triumph. The area of prediction in Bengal, N.-W. P., Central Provinces, and Punjab is rarely, if even without sufficient rain, except over

varying fractions of it; and the definition of average, or above or below average "rains," is one that the agriculturist is indifferent about, provided the distribution of rain over the season has been opportune or satisfactory. The practical value of a prediction is embraced just in these points—and on them the weather office is silent. A "rains" may be above the average—but a rainfall concentrated in July and August signifies drought when the *rabi* crop is to be sown, and that in turn implies a famine due within a twelve-month. A "rains" may be below the average, but its distribution so adapted to agricultural requirements as to ensure an ample *harif* crop and the foundation of the *rabi* or succeeding one. And so on for other conditions. Under these circumstances the only prediction that would prove striking or vindicate science, would be that of total or almost total failure of the "rains," *area being mentioned*. But the weather office has no knowledge of area; a prominent feature of this year's prediction too. Again, the forecast of a more than average "rains" this year for the Bengal, N.-W. P., Central Provinces and Punjab, cannot possibly imply that a uniform fall of so many inches will occur in each subordinate area with a known rainfall average registered at certain stations. The distribution of the rain is always eccentric. Large tracts may be deluged while others be imperfectly visited, or not have more than an average rainfall. So far then as details of area are concerned, a consideration that supercedes everything else, the prediction, even if confirmed as to the gross area, will be a failure.

Of late a tendency has been manifested in our Indian weather office to enlist phenomena in certain localities, for determining weather phases in contiguous areas—a significant admission that weather laws may be sought for elsewhere than in the fluctuations of the barometrical column. In June last, the office concealed its barometrical prediction of the preceeding May, of an "early rains" in Upper India. An unexpected snowfall in the Himalayas at the end of May was held to have vitiated the forecast. Such a phenomenon in previous years had, it was declared, retarded the "rains" through lowering the temperature in Upper India—or in other words causing there a rise in pressure. Monsoons like all disturbances gravitate only to areas of low pressure—which is the same thing as high temperature. On subsequent discovery, however, that the snowfall of May was only partial and that through not extending into the interior of the Himalayas, the requirements of departmental hypothesis of a retarding high temperature or low pressure had not been satisfied, the original prediction of an "early rains" in Upper India was restored. But the supposed inter-dependance of phenomena more or less separated by time or locality or both has never been justified by facts. That the weather office is, however, pledged to some such hypothesis is further proved by the following:—

"Weather report, Simla, 19th June 1883. * * A dry westerly and north-westerly current prevails over North-Western India, apparently repelling the moister monsoon current."

Here hypothesis seeks in co-incidental phenomena the relation of cause and effect. But even then what justification is there for preferentially making the westerly and north-westerly current a *cause* in this instance? How if the monsoon current repelled the other? That the dry area referred to was as much the effect of the atmospherical regulation at the time as the moist area beyond it, and that the dry and moist winds were simply concomitant features of the weather noticed there is not consonant with science at the weather office, because meteorological hypothesis has ever sought to discover *at the earth's surface*, the origin of weather-phases. The spectacle presented to the mind's eye of moist and dry winds contending for mastery, is as unscientific in conception as false in fact. At no point was there any conflict of winds in the instance mentioned, for the result would have been something of a cyclone. What happened was that each body of wind diminished in force towards a neutral area of calm of more or less extent, on reaching the confines of which it ceased. The phenomena is of constant incidence; during the "rains" more prominently than at other times. The hills offer the best facilities for observation. Flying acuda or clouds in masses of some extent from

the S.-E. or S.-W., travelling at the rate of 6 feet and more per second, may be seen dissolving or vanishing about a limit which the spectator may approximately determine by observation against the contour of a distant ridge. Whatever the force of the wind density or volume of the clouds, the latter will be found to travel very little beyond the point at which their dissolution is observed to commence. This will go on for an hour or more when the invisible cloud-vanishing line will recede or advance. But this forward or backward movement of the area of moisture by no means suggests repulsion by an invisible force, or repulsion of the latter. It is simply a self-adjustment to altering atmospherical conditions. As the wind is part and parcel of the phenomena, it presumably ceases too at about the cloud-vanishing line aforesaid. That wind and cloud are inter-dependent on atmospherical movements involving both, as in the above case, a noteworthy instance may be quoted. At day-break once on a sultry morning in an open agricultural tract, a rushing sound in the west drew attention to a low bank of clouds stretching unbroken from north to south (as far as the eye could see) and advancing rapidly. As it passed overhead, a brisk wind sprung up. The wind ceased as the cloud sped onward. But the rushing sound that was audible for some time after, proved that the wind was confined to the limits of the cloud, which was about 400 yards wide. The limits of the moist and dry areas and winds referred to by the weather office on the 9th June aforesaid, were similarly not regulated by conflicting winds, but by the operation of some occult atmospherical conditions which are always arranging areas of visible and invisible weather-phases.

There is demonstrable error in constituting barometrical variations and so called inter-dependant phenomena, the basis of forecasts. These are irreconcilable. In the *Pioneer* of the 18th June, an article, entitled "The Monsoon," desires to establish that the abnormal deviations of the barometer for March, April, and May last, serve as an index of the ensuing "rains." These deviations represent excesses or deficiencies over average pressure (masking influences being eliminated) for the months in question. Excesses are termed *positive* or *plus*; deficiencies *negative* or *minus*. The first indicate an approaching "rains" below, the second above the average. Now either this hypothesis for an ensuing "rains" is right, or that of inter-dependant phenomena. They cannot both be correct—for if positive and negative pressure are repressions or forecasts at all, it is not a matter of the remotest consequence what the character of Himalayan snowfalls is. The "rains" can neither be retarded nor accelerated, nor otherwise affected by them. But if snowfalls do have any such influence, then positive and negative pressure are meaningless. It is noteworthy that the department rates pressure somewhat low in assigning a vitiating influence over it by snowfalls. It therein perpetrates a scientific heresy, which although practically worthless is all the same welcome because degrading the much vaunted barometer.

The theory of abnormal pressures, however, requires examination on its own merits. If the abnormal pressures of March to May do not indicate current atmospherical conditions, but those for June to September, what do the abnormal pressures of these months signify? Logically, the weather for subsequent months—and not the "rains." But as the abnormal pressures for March to May were negative, a more than average "rains" will follow. Such a "rains," however, is impossible without the abnormal pressure during their incidence being also negative. It cannot possibly happen that the pressure during the "rains" will be positive, and the rainfall nevertheless conform itself to the negative or low pressure of March to May. Supposing however, that the relation between the pressure of March to May and that of the "rains" is established, then the undeniable inter-dependance of the "rain" with the "rains" pressure leads to the fact that the "rains" pressure is virtually indicated by the pressure of March to May. And this being the case, analogous relation of the October to December pressure with the "rains" pressure will be established; and so on all round the year. In other words, the abnormal pressure of March to May last which started into existence somehow, will be permanently

transmitted from season to season in succeeding years—thus making one year a counterpart of the other for all time to come, and rendering a weather office unnecessary—a logical *harri-kari* truly.

The abnormal pressure deviations of any period and locality, can refer only to that period and locality, and as it is an established fact that low pressure means high temperature and low temperature high pressure, the abnormally low pressure of March to May last was accordingly attended by abnormally high temperature, and the known inter-relation of pressure and temperature was thereby exceptionally illustrated—that is all. The weather office is doubtless justified in seeking a connection between preceding and succeeding weather-phases, because given conditions and their environments are necessarily the resultants of antecedent ones, but all the factors must be known for a reliable deduction. At present pressure constitutes the sole basis of inference. That all the factors required by present hypothesis will be discovered or determined is a possibility (of the remote future) but that satisfactory deductions from them will be practicable deductions rising to the dignity of laws, is not clear. It might prove more profitable to seek the origin of atmospherical laws in influences beyond the earth's surface, than in interminable combinations of factors of varying number and strength.

A. P. W.

THE SUPERIORITY OF INDIAN WHEAT.

MESSRS. McDUGAL BROTHERS, of Mark-lane, London, have furnished the Secretary of State for India with a very interesting report of a series of experiments with Indian wheat, which they were instructed to carry out. Four lots of Indian wheat, each of 5,000 lbs., were delivered to the firm, and the following instructions were laid down for their guidance in conducting the experiments. The instructions were—(1) that they should take a given quantity of wheat of each of these four representative Indian wheats,—viz., Indian fine soft white, Indian superior soft red, Indian average hard white, Indian average hard red—and manufacture them into flour by the ordinary process of grinding under millstones; that they should take similar quantities of the same wheats and manufacture them into flour by means of crushing between rollers, according to the system known as the Hungarian or roller system; (2) that a given quantity of each flour so produced should be manufactured into bread; (3) that the qualities and other characteristics of the flours produced, also of the offals, viz., middlings, pollard, and brand, should be noted; and (4) that they should procure the following representative wheats, of fair average quality of the season, as then being sold in Mark-lane Market, and for the purpose of obtaining results for comparison, deal with them precisely as above indicated, both as regards flour, bread, and offals, viz.—English average, American (red winter), American (spring), Australian average, Californian average, Russian Saxonka, Russian Taganrag, Russian Kubanka, Russian Ghirka, Egyptian Buhl, and Egyptian Said.

The experiments, we observe, were carried out in the firm's own mills, and were personally superintended by one of the members of the firm, a fact which goes no little way in adding to the value and trustworthiness of the report. The results attained have undoubtedly proved the superiority of the four lots of Indian wheat over the English and foreign wheats; and we cannot do better than state here for the benefit of our readers the leading characteristics of these wheats, as given by the firm itself in its report to the Secretary of State. We take the Indian wheats first.

Lot 1.—Quality, fine soft white wheat—(white, medium sized, skin thin, clean and regular, free from seeds; 2 per cent weevil; handled exceedingly well.) Value in London, 49s. per 496 lbs. Weight per bushel, 64 lbs. (This weight is only equalled by specially fine samples of any wheat.) Weight of 100 separate grains of the wheat, 55.4 grains avoirdupois. (100 weevil grains weighed only 38.69 grains avoirdupois.) Results of the milling and bakings prove it to be an exceedingly good and useful wheat; the flour being great in quantity, of pure white

color and superior bloom, and with a slight beany flavour. It is more suitable for markets requiring white flours rather than strength, owing to its containing an exceptionally low percentage of gluten. The yield of bread from it is very large.

Lot 2.—Quality, superior soft red wheat. (Colour, dull light brown, with about 5 per cent white wheat; size, half-medium and half-small; skin thin; weevil, only a trace; clean and free from seed; handled well.) Value in London, 45s. per 496lbs. Weight per bushel, 62½ lbs.; weight of 100 separate grains of the wheat, 51.8 grains avoirdupois. Results of the millings and bakings prove it is a good and useful wheat; the flour being great in quantity and of medium colour and strength, with a slight beany flavour, and containing an average of gluten. Suitable for markets requiring flours of medium strength and colour. The yield of bread is exceptionally large.

Lot 3.—Quality, average hard white wheat (colour, light yellow, and semi-transparent with a little hard red; size, long and arched; skin thin; wheat clean, but about 3 per cent of dry mud in large pieces; weevil only a trace). Value in London 44s. per 496lbs. Weight per bushel, 60lbs.; weight of 100 separate grains of the wheat, 68.3 grains avoirdupois. Results of the milling and bakings prove it is a useful wheat for markets requiring strength; flavour, beany; the gluten (by water test) averaging 12 per cent. This wheat and No. 4 are probably unsurpassed by any other wheats in the world as regards the quantity of flour yielded. In colour, medium. Specially useful for mixing with very damp English wheats to bring them into condition for milling. It is also a profitable wheat for millers, owing to its requiring 8.4 per cent water to render it sufficiently mellow for use. To this wheat and to the Indian average hard red (lot 4) must be awarded the distinction of *producing more bread than any other flour*, making it a "baker's" flour as well as a "miller's." The yield of the bread is exceptionally large.

Lot 4.—Quality, average hard red wheat. Colour, very dull brown, semi-transparent, with 10 per cent fine, soft, white, large, coarse grains, arched and pointed. Value in London, 43s. per 496lbs. Weight per bushel, 61½lbs. (condition clean and free from dirt, but a little grain, seed, and husked and barley; free from weevil.) Weight of 100 separated grains of the wheat, 77.7 grains avoirdupois. Results of the milling and bakings prove that it produces a common and dry strong flour, in almost unequalled quantity. In colour it is inferior. It is profitable wheat for millers, as it takes 7.6 per cent water to render it sufficiently mellow for use. The yield of bread is exceptionally large, making it a "baker's" flour as well as a "miller's." The same remarks apply to this as to lot 3.

Glancing at the results obtained with the English and foreign wheats, we find that the yield from the English wheat was poor, that from the Russian Taganroy good, and from the American spring and Russian Saxonska medium. The highest yields were obtained from the Australian, Californian and American red winter varieties, but even these were far behind the yield obtained from the Indian wheats. The two Egyptian varieties experimented with were apparently very inferior, the Saida being described as the poorest wheat in the market, possessing no good qualities and not nearly worth its price.

Two systems of milling were adopted in carrying out the experiments. That of grinding under millstones is said to produce flour of one "run" or quality, and does not offer facilities for the production of flours of high, medium, and low grades from the same wheat. By the grinding system some of the outer skin or bran is also torn or ground into flour, so preventing the attainment of perfection of colour. It is said to be well adapted, however, for the production of common ordinary flours, as it produces a greater quantity of flour than a system which more thoroughly separates the offals. By the roller system, flour is produced by flattening or squeezing the grain through a series of rollers, as distinguished from the tearing or grinding of millstones. The system is described further as follows:—"The wheat is first cracked through a first set of rolls and its sieve, so separating a small quantity of flour and dirt, the latter being liberated out of the crease of the wheat, and is not removable by any system of brushing or blowing. The cracked and purified wheat is then passed on through other sets of rolls and sieves, and rendered into middlings and flour." A leading feature in

this system which deserves notice is, that the germ of the wheat in which is the chief portion of the colouring matter of the grain, is not torn or ground into flour as it is by the system of grinding under stones, but the action of the rollers is to squeeze or flatten it, and from its soft and oleaginous nature, to increase its size, so rendering its separation from the flour easy. The advantages of this system are said to be, less liability to "kill" or destroy the granular nature of the flour, the removal of the dirt found in the creases of the wheat, and the separation of the germ, so rendering the attainment possible of a high standard in the character, colour, and bloom of the flour.

It is satisfactory to find Messrs. McDougall Brothers recording their opinion that the character and general excellence of the Indian wheats are improving with the deliveries of each successive season. Speaking of the particular consignments they have been experimenting with, the firm say, "that the Indian wheats now specially under review were delivered to us in excellent condition, with freedom from dirt (except lot 3), barley, gram, and other impurities, also with a freedom from weevil, rarely equalled by Indian wheats, except the prime parcels of the past season, and there is no doubt an outlet in this country and the European continent for unlimited quantities at prices that shall prove remunerative to all parties concerned, either in their growth, transportation, or conversion into flour and bread."

FORESTS IN ASSAM.

THE area of Government forests in Assam at the end of the year 1881-82 was 8,011 square miles, made up as follows:—

| | | |
|-------------------------------|-----|---------------------|
| Reserved forests | ... | 2,006 square miles. |
| Protected " | ... | 650 " |
| Other " | ... | 2,799 " |
| Forests beyond revenue limits | ... | 2,487 " |

The additions of the year were three new forests aggregating 50 square miles, which were brought on to the list of reserves. We observe that the question of bringing under reserves several other forests is under consideration, and it is perhaps probable that more work in this direction will be effected during the current year.

The results of fire protection during the year under notice do not appear to have been very satisfactory. Out of an area attempted of 105,212 acres, the failures amounted to 42,785 acres, or 41 per cent. The fires occurred chiefly in Goalpara and the Khasi Hills, where the injury done is reported to have been great. It is stated, however, that measures have been taken which will prevent the recurrence of such damage in the forests near Shillong, and it is hoped that similar precautions will be adopted in regard to the valuable sal forests of Goalpara.

Breaches of forest rules were not numerous during the year, and in this respect Assam compares very favorably with other provinces. The number of prosecutions was 37, against 40 in the preceding year. The majority of the prosecutions were on account of illegal appropriation of forest produce.

The area under plantations at the end of the year was 1,151 acres, as against 1,107 acres at the end of 1880-81. The total area was distributed in the following proportion:—

| | | |
|----------------------------|-----|-------------|
| Caoutchouc plantations | ... | 0.1½ acres. |
| Teak | ... | 170 " |
| Other | ... | 31 " |
| Sowings of Nahor and Ajhar | ... | 38 " |

The teak plantations at Kulsi and India-rubber at Balipara are reported to be progressing favorably. A very large number of the rubber trees at Balipara are now over 9 feet in height, and by constant care and attention they have been protected from injury. The licenses given during the year to extract rubber from the district forests, which were sold by auction, realised an income of Rs. 26,846. Some of the licenses are reported to have realised immense profits, in spite of the competition of foreign rubber, and of the facility with which the trees can be tapped in any part and the produce sold as foreign. Besides the Balipara plantation, there are a number of old rubber trees in the Chandwar reserve on which experimental tappings are to be made to ascertain what amount of juice can be safely

extracted, the age at which tapping can be begun, and the effects on a tree of judicious tapping.

It is stated that little forest work has yet been done in the districts of Sibsagar, Lakhimpore and Cachar. On this point the Chief Commissioner remarks as follows in his resolution in the Forest Report:—"The timber trade has not yet extended up the Brahmaputra Valley higher than Gowhatty, and there is little local demand for any other woods than the common kind. A new demand for sleepers has, however, set in through the construction of the Dibrugarh-Makum Railway and the Jorehat Tramway, and in the Lakhimpore district 4,377 trees were handed over to the railway, which has a concession for five years of all timber it requires. The royalty on these, had they been sold to the public, would have amounted to Rs. 18,410." The exploration of the large and little known tracts which it is proposed to reserve on the slopes of the Naga Hills, around Makum, and in the north Cachar Hills, was the principal work done in these districts during the year under report.

The departmental timber operations show a decline during the year. The total number of trees felled by the department was 378 as against 599 in the previous year. Besides those, 6,112 trees were felled by purchasers, and 4,377 trees were made over free of charge to the Assam Railway and Trading Company. The financial results of the year have not been satisfactory. The receipts amounted to Rs. 1,66,053 as against Rs. 1,68,997 in 1880-81 and the expenditure was Rs. 1,65,361, against Rs. 1,42,725 in the preceding year.

CANAL ARBORICULTURE.

THE report of District and Canal Arboriculture in the Punjab for the year 1881-82, shows that a fair measure of success was attained in the operations of that period. The length of avenues planted by district committees during the year was 380 miles, making the total length planted to the end of 1881-82 up to 4,008 miles. The extension of groves, nurseries, and plantations was also satisfactory; the total planted area for the whole province at the end of 1881-82 stood at 3,437 acres, as against 2,802 acres in the preceding year. Compared with 1880-81, the financial results of the year show a slight improvement; the expenditure amounted to Rs. 1,07,886, against Rs. 1,05,695 in 1880-81, and the revenue derived was Rs. 35,478, or Rs. 5,603 better than it was in the preceding year.

There seem to have been several methods adopted in the raising of trees. The general rule is that of raising them in nurseries, and transplanting them when they are from one to three years old. In the Delhi division, the tehsildars, it is said, adopt the method of sowing the seed in trenches; another plan adopted is that of sowing the seed on raised embankments; in Rohtak, again, the plan of setting out root-cuttings in worked earth was tried with success. It is satisfactory to learn that the efforts of the authorities to secure the interest of leading members of the agricultural community in arboriculture have not been wholly unsuccessful. In the Sialkote district, it is said that the people have already done much both in arboriculture and horticulture, while in Hazara the demand which is growing up for trees, which are distributed gratis, is taken as a sign of appreciation of arboriculture on the part of the natives.

Turning now to the actual work of the year, we see that the introduction and cultivation of vines and good fruit trees received much attention in Sialkote, Jhung, Dehra Ghazi Khan, and in one or two other districts. An attempt is also to be made to introduce the better kinds of plantains into the Punjab, where the present variety grown is a very poor one. In the Hoshiarpore district a new encamping ground was laid out at Damsuah; and very much was also done in planting out *nara*, *munj*, and *kuzi* grass for the purposes of protecting roadway embankments. The work in connection with reclaiming the "Cho" near Hoshiarpore was also continued, and according to the report, the results hoped for are "protection to certain low-lying mohullas of the town from floods, and the diversion of the channel of 'Cho,' which, if unchecked, threatens the existence of the town." In the Jhung district there are now a very large number of kikar plantations which supply wood for river steamers. These plantations are the property of

seminars, and we see a proposal in the report for purchasing some of the better plantations from their owners, in view to planting them out with *shishum* instead. From Delhi, Hissar, Jullundur, and Peshawur the reports of the work done during the year are also satisfactory.

As regards canal arboriculture, we see that the total length of avenues, as it stood at the end of the year, was 2,045 miles, against 1,949 miles in the beginning of the year. The financial results were satisfactory. The expenditure amounted to Rs. 32,541, and the income derived was Rs. 46,392. Speaking of the work done by the canal authorities, the Punjab Government's resolution, reviewing the report, says that "a large number of trees were planted on the Kasur and Sohraon branches of the Bareilly Doab Canal, and on the new distributaries of the Western Jumna Canal; and now that water has been turned into the Sirhind Canal, arboricultural operations will be prosecuted more vigorously along its banks."

EDITORIAL NOTES.

WE owe to the courtesy of the Lieutenant-Governor a copy of a letter which he has addressed to the Government of India, on the subject of the establishment of an Agricultural Department in Bengal. The letter is itself highly interesting and instructive, and the proposals set forth have a decidedly practical aspect. We are unable to comment upon it in the present number, but our readers may see it reviewed in the *Statesman* of the 25th and 27th ultimo.

Mr. D. MORRIS, the Director of Public Gardens, Jamaica, at the request of the Government, recently visited British Honduras to examine the flora and agricultural resources of the colony. The following is his preliminary report:—

"With regard to my visit to British Honduras, I was enabled, by the assistance and courtesy of the Government, to travel through all the southern settlements: and while making observations and carrying out the wishes of the local Government, I had very favourable opportunities, (assisted by the native collector whom I took with me) to make valuable collections of seeds and plants for the Public Gardens of this island. The chief plants of interest gathered were several species of *Palms* (*Chamædorea*, *Bactris* *Sabal*, *Chamærops*, &c.) which were not previously in the Jamaica Gardens: seeds of numerous timber trees and flowering plants: and a valuable collection of decorative orchids, including the indigenous large growing *Vanilla* of Central America. This latter has pods much larger and more aromatic than the ordinary *Vanilla* cultivated in Jamaica, and I am hopeful that it will be largely propagated and distributed in the island.

"After returning from the south, I next visited the central and western districts of the colony. This country generally (with the exception of a few isolated ranges) rises so very gradually from the sea coast to the interior that points on the western frontier, nearly one hundred miles from the coast, are only three hundred feet high. This low, gently-sloping land, is plentifully intersected by deep navigable rivers which flow slowly towards the sea. Along the banks of these rivers, the characteristics of the soil and climate were of a most favorable character, and the vegetation essentially tropical and luxuriant. Passing across the country from the river district to another, a section was traversed composed of a poor quartz soil supporting only a sparse vegetation of *Pine* (*Pitch Pine*), evergreen oaks, and a low shrubby palm (*Chamærops* sp.). On further acquaintance with the interior portions of the country I found that the alluvial deposits along the river banks extending some five or six, or, in some instances, some ten miles on each side, contained, chiefly, the rich valuable soils of the colony. Beyond these were 'broken lands' and 'pine ridges.' I estimate that fully one-third of the area of the colony is composed of 'pine ridge.'

"The most important as well as the richest river valley in the colony is that of the Old River, sometimes called the Belize river. This extends in a wide sinuous course from the town

of Belize at the sea coast to the western frontier : in the upper portions, the valley widens into broad expanses of rich fertile plains covered by cohune palm, in some cases, thirty or forty miles in breadth. I carefully examined this district and worked my way to the frontier station—the Cayo—near which a coffee plantation has recently been established. With the exception of some six sugar estates and the same number of banana plantations, this coffee plantation is the only attempt, hitherto made, to establish a systematic course of culture in the colony—the bulk of the people being employed, and the chief trade of the colony depending upon mahogany and logwood cutting, which, when good prices are ruling, are apparently very remunerative industries.

"In the forests of the western districts, I found the rubber-tree of Central America (*Castilloa elastica*) very abundant. This tree (a member of the Breadfruit family) is specially suitable for cultivation on account of its preferring a loamy sandy soil ; and being a deep feeder it might be utilized as a shade tree in cultivated areas with great advantage. I spent two days with a rubber gatherer in order to observe the methods of bleeding the trees and preparing the rubber ; and I brought with me botanical specimens of the tree, some seed, as well as a sample of the rubber. I hope soon to make a special report on this tree and its produce. I am, also, making arrangements to procure a large quantity of the seed, when ripe, for distribution amongst cacao planters in this island. Trees at ten years old yield from four to seven pounds of rubber, which is valued at from 2s. 3d. to 3s. per pound. If carefully managed, the trees can be bled every three or four years.

"Another interesting plant found wild in these forests was the indigenous cacao of Central America : this differed from all kinds I had met previously. After careful inquiry, I found that it was the 'Tampasco cacao' of the Atlantic slopes and identical with the celebrated 'Socunusco' of the Pacific coast. In habit and character, the trees approach those of the *Cacao Oriollo*, and an examination of the pods which are of a golden-yellow colour led me to the conclusion that this 'Tampasco' or 'Socunusco' cacao is the yellow form of the celebrated 'Caracas' cacao. Should such prove to be the case, there is little doubt that this yellow variety will prove as much superior to the red (Caracas) form, as the yellow Forastera does to the red (Trinidad) cacao.

"Many other interesting plants of timber and dye-woods, as well as of plants of medicinal and economic value, were met, many of which I have no doubt are capable of being utilized both in British Honduras and in other British possessions. A detailed account of these will more fittingly be included in a report which I am now preparing on the scientific result of my visit.

"In returning from British Honduras, as mentioned in the second paragraph of this letter, I had to take steamer to New Orleans, and I was detained there nine days waiting for a steamer for Jamaica. I took advantage of this opportunity to visit the sugar estates on the river Mississippi ; and among other kinds, I found that the celebrated Lohina cane of the Sandwich Islands (lately introduced to Jamaica from Mauritius) was under cultivation on one estate and was very favourably reported upon. I brought with me specimens of the best canes from Louisiana which have been safely established at the Hope Plantation.

"The best Louisiana sugar-canes are as follow :—

"*Lohina Cane* : brought from Sandwich Islands by Dr. Richardson and cultivated at Belair Plantation on the Mississippi River. Reported upon favourably by John Dymond, the proprietor ; small flag ; grows well and yields good sugar ; does not, however, ratoon well. See Mr. Horne's Report on the same cane received from Mauritius last year.

"*Louisiana Otahelie Cane* ; formerly much grown in the Southern United States, now mostly superseded by the Red Ribbon and Violet canes : it does not stand the climate of Louisiana so well as either of the latter ; comes up later ; matures later, and ratoons less well. In favourable (i.e., warm) seasons or under favourable conditions (i.e., near the sea or banks of rivers), it produces larger tonnage than either Ribbon or Violet canes, but is rarely so sweet as either. It is a tender cane for these latitudes, and easily affected by frosts.

"*Red Ribbon Cane*.—The sweet Louisiana cane ; hard shell, broad leaf : a general favourite amongst planters, but is reputed without sufficient grounds to degenerate into the red cane : yields largely in quantity of cane and works well into sugar : does not stand frost so well as the violet cane, but is, on the whole, considered the best cane for Louisiana.

"*Java Cane*.—Very similar to Otahelie : was brought to Louisiana about 1870. Stands frost better than the ribbon cane and ratoons well. Said to be a rich cane, yielding sugar largely."

In a paper read at the last annual meeting of the New York Agricultural Society, H. E. Alvord summarizes the conclusions thus far obtained upon the subject of silos and ensilage : Silos of moderate size are convenient and economical on almost any farm, to preserve green any forage crop which circumstances prevent curing, or some crop specially grown to supply succulent food in the winter. Silos may be built with much less expense than has been generally supposed, and that, upon their location and arrangement, the economy of their use very largely depends. This system of storing forage may be pursued almost regardless of weather, and may be arranged so that the chief labor comes at a time when other farm work is not particularly pressing. With proper care the process of ensiling will preserve green forage substantially unimpaired as food, but with a probable increase in the percentage of protein and more or less loss in the carbohydrates. As cattle food, ensilage forms a cheap substitute for roots ; but the crops generally used fail to fill the place of the root crop in a judicious farm rotation. In feeding ensilage, the best results follow a moderate system, rather than its entire substitution for dry, coarse fodder. The most marked result in ensilage feeding is the general condition and health of the animals, just as in the case of any succulent food. The extensive use of ensilage upon any farm is mainly a question of convenience and economy dependent upon the local conditions.

Last year a farmer improvised a small silo by sinking a molasses hogshead into the ground in his barn cellar. He cut up all his corn fodder with a hay-cutter, supposing he had enough to fill about four hogsheads, but on packing it found it wouldn't fill one. He then bought of a neighbour as much more as one horse could draw, and still there was room. He then cut up the stalks from a piece of sweet corn, and with a lot of rowen managed to fill his hogshead. He made a close fitting cover, and with a jackscrew set under one of the floor timbers, pressed it down as tight as possible. In the middle of December he opened his silo, and found the corn as sweet and fragrant as when put in. From the hogshead he fed one cow half a bushel of ensilage morning and night for two months, and considers it the best producing food that can be had. This year he proposes to fill the hogshead with oats cut just as they are in the milk. If a silo on so simple a plan is practicable, there is certainly no reason why everybody should not have one, and satisfy himself of the value of the ensilage system.—*Nashua Telegraph*.

The latest addition to the literature regarding the *divi-divi* tree is an interesting paper by Mr. C. M. Smith, of the Public Works Department, at Masulipatam, in the Madras presidency, which has recently been published by the Local Government. Mr. Smith's remarks apply to the variety of the tree as growing in Masulipatam, and he writes as follows :—

"Height of tree, 15 feet ; boughs commencing at about 2 feet from the ground, straggling and wide-spreading, from 10 to 15 feet in length ; unarmed ; bark of a dark brown grey color, and very rugged.

"*Leaves*—bipinnate, three or four on a twig, 6 inches in length, with from six to eight pairs of pinnae—pinnae being 2 to 3 inches long ; *leaflets* paired and numerous—as many as twenty-eight pairs to a pinna, but varying in number in different leaves, and on the several pinnae ; length $\frac{1}{2}$ inch, breadth 1-16th inch.

"*Flowers*—in clusters, of a pale green-yellow; very strong, but agreeable scent. Blossom in the cold weather (twice from December to February); seed ripens in March (second crop.)

"*Pods*—curly, of a dark red-brown color and hard; an average pod contains five or six seeds, small, oblong, smooth, and of a tawny color. The length of such a pod is $2\frac{1}{4}$ inches, and breadth over $\frac{1}{2}$ inch.

"I should have mentioned that the leaves commonly have one terminal pinna, but frequently terminate in two, i.e., in a pair of pinnae.

"There are ninety trees in this garden of different sizes, most of which are producing seed, besides two or three young self-sown plants. There is no difficulty in propagating the tree; it comes up readily self-sown.

"The trees in this garden are, I am informed, about 38 years of age, having been planted by a Mr. Dick, port officer.

"The soil is almost pure sand; the roots of the trees probably reach good water, which is found not far from the surface.

"The poor nature of the soil probably accounts for the small size of the tree. I say 'probably,' because the small size is, I think, mainly due to the trees being planted too close together, in many instances there being little more than 6 feet of space between the trunks. The girth of the best-grown trees at a height of 1 foot from the ground, I find to be about 2 feet 6 inches. The trees, however, are mean in appearance, though luxuriantly covered with foliage at the right seasons of the year. They never entirely lose their foliage.

"With regard to the produce of trees, I note as follows—The total quantity of seed in pod produced in the one crop which I have lately had collected amounts to 43 sacks of 71 lbs. each, or 3,010 lbs., or 1.33 tons. I find that $\frac{1}{2}$ oz. seed is obtained from 1 lb. of full average-sized pods, i.e., the seed bears a proportion in weight to the pod of 1-18th nearly. In one average-sized, well-developed pod, I find seven seeds; in another six. Eight hundred seeds nearly go to the ounce, i.e., 12,800 to the lb. of 16 ounces. A 70 lb. sack of pod occupies in bulk a space 28 inches and 18 inches diameter—nearly 4 cubic feet, and thirty-two sacks = 128 cubic feet = 1 ton.

"In regard to the value, I have never systematically endeavoured to sell the seeds and pods. There is no great demand for them here I believe. I believe they are not exported. They are, I know, used to a limited extent by the local chucklers or leather-workers in tanning and coloring leather."

Mr. J. G. Horsfall, the Collector of Kistna, in submitting Mr. Smith's paper to the Board of Revenue, has recorded the following observations on it:—

"Mr. Boileau, my forest assistant, has been directed to commence planting up one of the forest *topes* with the *divi-divi*. The tree grows fairly well in this district, both close to the sea, on sandy soil, and inland. Our avenues of trees on the Hyderabad roads seem to have flourished better than those in Mr. Smith's compound in Masulipatam. I expect that it will be largely grown as soon as its value becomes generally known, and I am informed that plantations of it are being started by some enterprising natives in the Bapatlo taluk, who had taken up land for casuarina plantations, after witnessing the result of the casuarina plantations started under the jungle conservancy.

"I see no reason why in a few years this district should not be able to supply any quantity of the pods. The tree, however, is a slow-growing one, and I regret I cannot state from personal observations at what age it first begins to yield."

We have received a copy of the "Descriptive Catalogue of Indian Produce contributed to the Amsterdam Exhibition," by Baboo Trailokya Nath Mookerjee, the officer in the Department of Revenue and Agriculture who was intrusted with the organisation of the Indian collections for the Amsterdam Exhibition. This list has been arranged alphabetically according to the modern scientific names, and has, in addition, a complete index to all its English and vernacular names. Apart, therefore, from the primary purpose for which this book has been written, it is to the credit of the author that he has so thoroughly done his

work as to give us an easy book of reference on the subject of Indian produce. He has produced a neat volume of 190 pages, sure to become a standard of reference in future. As a catalogue it seems to have one defect, however, and one which it was most probably impossible to obviate, namely, there is no mention of the numbers attached to the specimens. This difficulty it is doubtless intended should be overcome by the visitors getting possession of a copy of the Official Catalogue of the Exhibition to be used along with the descriptive catalogue.

We think the manner in which each product has been treated exceedingly good, and the style and get-up of the work excellent. After the scientific name is given a small paragraph containing the leading vernacular names. Then follows a brief account of what might be called the properties and uses of the product. On the margin are stated the uses to which each product is put. For example, if the visitor wishes to learn something of the medicinal virtues of a plant, he has only to run his eye down the marginal notes to the word "Medicine," opposite which will be found the information desired. We note in the preface that the author acknowledges "his obligation to Dr. George Watt who kindly consented to correct the final proof-sheets, and thereby many inaccuracies in botanical terminology have been obviated." This is a guarantee that the scientific names are those in use at the present day. Until the reports of the Amsterdam Exhibition appear, it would be premature to comment upon the manner in which Baboo Trailokya Nath Mookerjee has discharged the duties intrusted to him as "Officer in charge of Indian Exhibits," but judging from the completeness of his "Produce—Descriptive Catalogue," we should expect to hear favourable reports on the Indian display at Amsterdam. We may mention that Baboo T. N. Mookerjee is at present the officer in charge of the Exhibition branch of the Revenue and Agricultural Department in connection with the approaching Calcutta Exhibition.

The following passage is from the United States Consul General Mattson's Report:—

The Indian agriculturalist—ryot—can in no sense be compared to the American farmer, but rather to the late serf of Russia. He is a tenant on hard conditions, and is, by custom and bigotry, almost a fixture on the particular spot of land where he was born; his farming is done on a very small scale and according to old methods, to which he clings with religious veneration; his wants are very few, and he endures poverty and even hunger with patience; he cultivates his patch of five to fifteen acres on shares for the landed proprietor—zemindar—who holds under rental to the Government, and the better half of his gross income generally goes to the zemindar, the priest (Brahmin), and the usurer, in the form of rent, presents offerings, and interest, and if he cannot ten cents a day by his hard and hopeless labor, that will suffice for the most pressing wants of his household. His home is a mud or bamboo hut; his property a pair of small bullocks, a few cows, calves and goats, a wooden cart, and a few brass and earthen pots—in all worth about \$50; and his implements and tools are of the rudest kind, such as his ancestors used a thousand years ago, and yet he is making some progress under British rule, and finds his wants increasing; at the same time better outlets for his produce and more recompense for his labor, and, on the whole is so independent on 10 cents a day that he will eat or store his wheat rather than sell below a certain price. Of course, he does not employ machinery in farming, but ploughs his land with a crooked piece of iron-pointed wood, harrows it with an implement resembling a common ladder laid flat on the ground, and dragged by the little bullocks crossways over the field he sows by hand, reaps with a rude sickle, carries the sheaves home on his back or in the bullock-cart, threshes them with a wooden club, or lets the cattle tramp out the grain, and cleans it by hand winnowing.

A flock of sheep running in the orchard is said to be the best practical protection against the ravages of the codling moth. They pick up and eat every wormy apple that drops, before the grub has time to get out of it, and so prevent their propagation. In an orchard thus pastured by sheep through the

summer, Mr. A. R. Whitway, an experienced American nurseryman, found the fruit on gathering almost uniformly sound, while in another part of the same, and separated from it only by a hedge, and of the same varieties of fruit, but not pastured by sheep, the fruit was as uniformly wormy. But every one cannot make a sheep pasture of his orchard or fruit garden. Next to this, he recommends what has already been widely published, the hanging in the trees of wide-mouthed bottles, like quinine bottles, partly filled with sweetened water, with the addition of a little vinegar. These will attract and trap the moth in large numbers. The ant, he also states, is a valuable auxiliary that can be utilised in fighting this pest. It is a carnivorous or flesh-eating insect, and will clear trees of insect foes in the vicinity of its nests. He suggests the planting of ant-hills in the orchard, by taking a spade full from an old hill and planting it in a hole in the ground. His objection to the use of torches to attract and destroy the moth is that you are liable to destroy friends and foes alike.

PROFESSOR A. J. COOK, of the Michigan State Agricultural College, has made extensive trials with arsenical compounds as a means of destroying the codling moth. It has been a matter of general experience that when Paris green or London purple has been used on potato vines it is soon washed off, and the mixture has to be frequently applied. Professor Cook fails to find any difference between the two above-mentioned insecticides. A half-ounce of either to a gallon of water is quick death to insects when spread over infested foliage. He also found that a weaker mixture, one pound of the arsenate to 100 gallons of water, was effective.

Experiments were tried to find out how long the poison remained upon the foliage exposed to ordinary conditions of rain, wind, &c. A brisk shower was found to render the poison useless. This has been the experience of many. We have found, says a contemporary, that the only profitable time is to apply the arsenic after a shower, or while the vines are wet with the dew, and if a hard rain soon follows the work needs to be done over again. Professor Cook found that insects suffered no harm by eating foliage after twenty days' exposure, and in most cases fifteen days were enough to remove the poison sufficiently to render it inoperative. When the plants were kept from the winds the time of action was much extended.

The test of the microscope was applied in all cases, and it was found that the poison had been removed from all smooth parts, and only small portions remained in holes and out-of-the-way corners. The poison is removed by chemical means, wind, rain, brushing of leaves against each other, &c., and not by being absorbed into the substance of the plant. This last is proved by careful chemical analyses that have been made to detect any traces of the arsenical compounds.

Professor Cook not only concludes that much more of the poison is used than is necessary. We may add that the importance of frequent applications is fully sustained by all these experiments.

Pyrethrum powder is safe, and should be used instead of the deadly arsenical compounds on all garden vegetables, the foliage of which is eaten. Cabbages, lettuce, strawberries, &c., belong to this class.

The insects that infect the fruit and foliage of trees may be safely destroyed by a dilute mixture of the Paris green or London purple. With these the fruit is usually picked a long time after the poison is used. It is seen that we have a remedy for the codling moth that all may use. Any force pump can be employed for spraying the trees. The nozzle fitted with a fine nose may be arranged upon the end of a long pole, and in this way the poison mixture is brought to all parts of the tree.

THERE is a right and wrong way to make a hole in the ground, and set out a plan, says a contemporary. Some persons remove ten times the necessary amount of earth, and do not give the plant a good setting as one does it in one-tenth of the time. Small plants of vegetable and flower garden are best transplanted with a sharpened stick or dibble. This simple implement should have a bend for a handle like that of an umbrella or cane, only less.

It should be thrust perpendicularly into the well-prepared soil, there rotated and removed. The left hand at the same time picks up the plant, and after picking it in the hole, the dibble is pushed into the soil to one side, and in a slanting position, starting about three inches from the opening and running to meet with the bottom of the first hole. By pushing against the dibble and bringing it towards the plant, the earth is pressed up properly, and the work is quickly and well done.

THE Nallamalai forests contain large valleys with good soil and covered with forest of teak. Yagi (*Petrocarpus Marsupium*), Nallamaddi (*Terminalia tomentosa*), and Blackwood (*Dalbergia latifolia*), while fine trees of other kinds, likely to prove valuable in the future, yield a cover which keeps the soil moist, and ensures a good reproduction. The hill slopes are naturally drier, but, still, will supply a large amount of bamboo as well as quantities of Chiriman (*Anogeisus latifolia*) and other good wood used in the country. The proposed railway line from Tadpatri or Adoni to Guntur will pass through the forests by either of the two great main roads, the Nandikanama and Mantralakanama (Dornal Pass), and will be enabled to draw large supplies of fuel from them, which can easily be arranged for under a regular working scheme to the benefit of the forests. At present a considerable amount of wood is taken out, and finds its way to the less well-supplied districts of Bellary and Anantapur, and even further, and the Kurnool-Cuddapah Canal can probably be made use of to extend the area to which produce can be taken.

"How many young men," says the *Farmer's Review*, "ever think of studying practical farming with some successful farmer? An old farmer—he was old in experience rather than years—called on us the other day, and talked an hour of his experience in draining lands, raising sheep and horned cattle; the breeds he had kept, and the best for such and such purposes; of his experiments with the several varieties of apples; of how he "learned the poultry business," &c., &c. "Now, is it going far out of the way to say that not one young man in a hundred, who to-day proposes to follow farming the rest of his life, seriously thinks of going out to live a year or two with one of these practical farmers, so as to learn the business? When a young man proposes to follow the law or medicine as a profession, he goes to some good lawyer or physician, and spends a year or two in 'reading' law or medicine. Now, why should not a wide-awake, energetic, ambitious young man study farming with some practical farmer who tried all these experiments? We think at the end of one or two years the young man would know absolutely more of practical farming than he would learn by himself in ten years. In other words, he would start out as a young farmer nearly where the older man of whom he learned stands to-day. If the young man makes a success he has got these things to learn, and learn by experience, too, and why not study with some good, practical, thorough farmer—go and work on his farm as a hired man. We found a graduate of the Massachusetts Agricultural College a few years ago as the hired man of a practical, successful, and thorough farmer, studying farming. We met a young agent of the French Government studying farming in America in the same way. He had worked with practical farmers in the great cheese regions of New York, with the cattle-men on the plains, and was on his way to the frontier for further study."

Will the day ever come in India when the sons of zamindars, and others interested in Indian agriculture, will take to a similar practical fashion of acquainting themselves with the agriculture of their own land?

THE following note on deep versus shallow ploughing is from the *Farmer's Review*:

Agriculture has not as yet become a fixed science. While certain principles have received general recognition, in regard to other matters, theory and practice are constantly undergoing changes, as superior practical results are wrought out by a departure from established methods. Not so very long ago, the theory and practice for using manure was to plough it under as deeply as possible. Now the surface application is most in practice. Deep ploughing has been associated with the idea of

good husbandry, and shallow with its opposite, and it would have required a good deal of moral courage for a farmer who took pride in his work to acknowledge that he ever ploughed land for a crop only three or four inches deep. He would have been a loser in reputation among his neighbors by such an admission.

It seems now to be pretty well established by practical results that, under some conditions, the farmer who ploughs deep does it at the expense of the crop, for that season at least. Theories based upon established facts, or which can be proved true by practical results only, have value. Before giving our theory on the subject of deep or shallow ploughing, we give one or two practical results recently brought to our notice. The first is a statement by a correspondent of the *Journal of Agriculture*, who says: "I ploughed eight acres last spring about eight inches deep, harrowed it fine, and it was as nice a bed for planting as I ever saw. Well, I planted it early, that is, early enough, and then I worked it with my riding plough pretty deep, and it was pretty clear of weeds. There was a fellow on the other side of the fence, with a very light plough and light horses which were not able to plough more than three inches deep. When he worked it he did it mostly with a narrow-bladed scraper that would scarce go into the ground at all. But what surprised me the most of all was, that when we husked our corn, that chap had ten bushels more to the acre than I had."

About the same time that the above fell under our notice, the Hon. Samuel Dysart, of Franklin Grove, Ill., a member of the State Board of Agriculture, gave the results of an experiment of his own in deep and shallow ploughing. Last spring, in preparing a field for corn, he ploughed the alternate lands deep and shallow—the one as deep as a heavy team would turn the soil, eight or nine inches—the other, not to exceed three or four inches. In planting, he planted across the lands, so that there should be no possible difference in the seed, manner of planting, or cultivation. The corn on the shallow ploughing came up nearly a week ahead of that on the deep ploughed land; it continued growing till near maturity, when the latter took a start, and shot up two feet above that on the shallow ploughing, and was still growing when the frosts came, and gave no sound corn, while that on the shallow ploughing all matured. Now for our theory. The deep ploughing brought to the surface a soil not probably lacking in the elements of fertility, but which having been buried under six to eight inches of soil, was not in condition to furnish plant nutriment until it had undergone a chemical change, through the action of the air, sunshine, rain and frost; while the surface soil, which had been subjected to these influences, was turned under so deep that it was not available as plant nutriment, certainly till near the close of the growing season. The shallow ploughing gave a seed bed of the surface soil, which furnished plant nutriment from the start, and thus ensured an early growth and maturity of crop. The conclusion to be reached is not that ploughing should be uniformly shallow, but that deep ploughing should be done in the fall. When so done, the soil exposed to the action of the elements during the winter will be properly prepared for a seed bed in spring, when but a shallow stirring need be given it. But if ploughing is delayed till spring, deep ploughing at that time will be at the expense of that season's crop. While it is unquestionably true that all soils should be worked deep, it is a question worthy of careful experiment whether this is necessary every year, or whether, say on alternate years, a shallow stirring of the surface to the depth of three or four inches by some implement which will do the work much more rapidly and cheaply than the plough, will not bring equally good results with a saving of time and labor. Such experiments, to be of value, should be on soils of different quality and texture and on the different crops grown by the farmer. We suggest this subject to those in charge of our agricultural colleges and experimental stations.

DARLINGTON is one of the few towns in the north of England owning a sewage farm, and the statement of its accounts just issued for the financial year ending in March is (says the *Newcastle Chronicle*) interesting, because there can be no doubt that many

towns on river sides will some day be forced, as was the town on the Sharpe, to divert their sewage from the stream and utilize it on the land. This course was forced upon Darlington some years ago. It bought land and formed a farm to utilize the sewage at a cost to the present of £100,645. In the financial year just closed it spent £7,305 on the farm, including £4,081 for interest on and repayment of loans. The receipts were £7,805, inclusive of £5,000 from the borough rate, so that the farm paid its way as a farm in spite of the bad harvests, but the town has to pay the interest on the money borrowed, and this is the cost to it of keeping the sewage out of the river. There are 50 cows on the farm, and 100 cattle, sheep, and pigs; so that Darlington Corporation is a farmer on a tolerably large scale. But Darlington has in its own hands the gas and water works that supply the borough. These works have cost the borough in round numbers £200,000. Last year the receipts were—Gas works, £19,853; and water works, £8,905. Both left very handsome sums to the profit of the works. After paying the interest on the loans there was a credit balance from the working of the two of £8,157, so that they pay much more than the interest on the loans on the sewage farm (repayment of principal being for the moment left out of the question). In other words, taking repayment of debt into account, if the people of Darlington would use a little more of the cheap gas their works make, and the water they get for the asking from the Tees, they would from the profits gradually redeem the works from the loans upon them, pay the interest on the sewage farm, and ultimately free the latter from its mortgage.

BEE-KEEPING IN INDIA.—On this subject, a correspondent of a Calcutta paper, after relating several facts regarding the domestication of bees in several villages of the Hooghly and Burdwan districts, says:—

"Perhaps you may not be unaware of the fact that the respectable Dutta family of Nimtollah owns an estate in east Bengal, which is chiefly valuable for the cultivation of bee-hives amidst the water-lily plants. The honey collected from these hives is generally known as 'bly-honey,' and is sold at Calcutta and other places at a high price. From these facts, I am of opinion that if the scheme is favourably supported by the Government, and the people are encouraged to extend bee-keeping, it will certainly take a footing among the paying industries of the country."

A CORRESPONDENT writes to us that the cultivators, who form about 75 per cent of the population of the N.-W. P., never dream of using chopped timber for cooking purposes unless at weddings when they collect it for months if not years previously, and then use a certain percentage of cowdung with the wood, or at funerals, when the whole village often combines to furnish the fuel. Cowdung is also used here—a little of it. The average cultivator holds about 10 acres, 5 of which bear fuel crops, for they chiefly use arhar, cotton, and castor stalks where flame is required; cowpats are used freely for everything, and by mixing straw with the cakes, they can be made to burn with a flame without the unpleasant smell of burning straw. At a low computation five acres give 25 maunds of fuel annually, and as the average cultivator also owns a pair of oxen and a cow buffalo and calf, and he will also have, if his wife is industrious, about 75 maunds of cowpats—a great deal of cow-dung is lost when the cattle are in the fields, and in the dry weather this is the potters' perquisite. In all, 80 maunds, or 10 acres of fuel daily, if he requires so much, and he does not by any means, often selling his fuel and using his arhar and cotton stalks freely for wicker linings for his walls.

Those that are not cultivators, send their children to pick sticks in groves, and collect madar stalks, useless thorn tree dges, &c.

The *Farmer's Review* has the following note on changing the bearing year of apple trees:—

Most varieties of apples bear only on alternate years, giving an abundance of fruit one year and little or none the next. But this bearing year in a tree can be changed by removing the blossoms on the bearing year and allowing it to bear no fruit, when it will make a set of fruit buds and bear the next year. In a young orchard this habit can be noticed and

changed by the above method on a portion of the trees, at the expense of but little labor, so as to have a part bearing fruit every year. With a step-ladder and pair of shears the work can be rapidly performed. It is not too late now, even if the blossoms are gone and the fruit set. Its removal is as easily accomplished, and with the same result.

THE report by Prof. Henry of "Experiments in Sorghum" at the experimental farm of the university of Wisconsin, of which a brief summary was given in a recent issue, contains also voluminous extracts from correspondence from sorghum growers and manufacturers throughout the state upon methods of cultivation, manufacture and cost value of seed, skimmings, &c., a few of which we subjoin.

O. S. Powell, of River Falls, on the subject of skimmings, says he runs them into tanks to be made into vinegar. He says: "We make the best of vinegar by merely giving it time to work, and then pass it from one tank to another for the purpose of straining and filtering. Six thousand gallons were made last fall in this way that by the first of June will be better vinegar than is obtained from any other source, not excepting old cider or maple sap." This vinegar is made at scarcely any appreciable cost, and the idea is well worth being adopted by other syrup makers.

Ambrose Warner, Whitewater, says: "I fit my land as though I were going to plant it to onions, then I always get a good stand. Go over with a drag last; that fills up all the horse track and leaves it ready for the planter. * * * I plant three feet eight inches between the rows, and from two and-a-half to three feet in the rows; plant about one inch deep; drag before planting. When the cane is up bring the shields (on the cultivator) within two inches of each other, and by driving slow can do a nice job as I have no lumps to bother. When the cane is two or three inches high, clean out the weeds in the hill, then cultivate same as corn. When ready to cut I take a saw-buck, made longer than for sawing wood, set it between the second and third row, cut four rows and throw on the horse. When I have enough for a bundle, bind it and cut off the tops with one blow of the corn knife. Then lay the bundle over next the standing cane, and so as to have the bundles of next four rows cut laid on them. Bind and set up my seed heads, then rake up the leaves stripped off with a horse rake."

Edwin Blood, Stockbridge, on the subject of manufacture, says: "Heat the juice in the desecator to about 150 degrees; add milk of lime until the juice shows by blue litmus paper slightly acid, or until the paper shows a light pink color. Heat rapidly until the scum turns dark colored. Let it stand a few minutes, then draw into evaporator; then skim and evaporate as rapidly as possible to 228° or 230°. * * * If above instructions are carried out, one cannot fail to make a light colored, clear syrup perfectly free from that detested sorghum taste, and which will sell at any time in any market."

As for the cost of making syrup much depends upon the state of the weather, ripeness of the cane, machinery and help employed. In the fall of 1881, it cost me 11 cents per gallon for manufacturing, and the past fall (1882) only 7 1/6 cents per gallon.

Evan Erickson, of Stevenson, P. O., La Crosse county, submits a detailed statement of total cost of raising and manufacturing ten acres of cane, which, being condensed to save space, looks up as follows:—

| | | |
|--|-----|----------|
| Preparing the ground... | ... | \$ 20.50 |
| Planting and cultivating | ... | 36.00 |
| Harvesting and hauling | ... | 55.37 |
| Labor and fuel in manufacturing... | ... | 132.00 |
| Board of men and teams | ... | 81.55 |
| Barrels for syrup | ... | 31.00 |
| Hauling syrup to market | ... | 31.00 |
| Total cost | ... | \$387.42 |
| Cr. by 1,570 gallons syrup, sold at 40c. | ... | \$628.00 |
| Deduct expenses | ... | 387.42 |
| Net profit | ... | \$240.58 |
| Net profit per acre | ... | \$ 24.05 |

Hollister S. Phillips, of Mindoro, La Crosse county, writing of the value of seed, says: "The yield of seed, as near as I could estimate, was twenty-two bushels per acre. * * * One hundred and eight pounds of seed yielded sixty-six pounds of flour. We used cane seed flour in our family from the time of threshing in November till the next August. For griddle cakes it is nearly equal to buckwheat (some of our neighbors claim it is superior), and mixed equal parts with buckwheat we could see no difference. For soft ginger cake it is excellent. * * * As a feed for cattle, horses, and hogs I know it has no equal. There is no grain that will make horse gain in flesh faster. For milk cows a person cannot estimate its value till he has tried it. It is especially valuable for young stock and calves and for hogs. I know that it is worth more per bushel than corn, and when I say more I mean that there is a great difference. In the spring of 1881 we killed a hog that had been fattened wholly on cane seed. The meat was as hard and sweet as ever tasted. This hog was fed on nothing but cane seed and water, yet it took on flesh faster than any hog I ever fed."

THE following is the substance of Dr. Aitken's report read before a recent meeting of the Highland and Agricultural Society:—

"I have to report regarding the progress of the work of the chemical department that the experiments at the society's station have been successfully laid down. The crop this year is barley, succeeding turnips, and though there is a healthy braird to be seen, yet the long drought has to a considerable extent prevented the manures from coming into operation. Crops to which only light manures are applied suffer most from drought, and it will be some weeks before the experiments at the stations will be worthy of a visit. In addition to the general scheme which has been followed from the beginning, the plots on the stations have in most cases been divided into two parts, to show the different effects of nitrate of soda when applied with the seed and when applied some weeks later. A few odd plots have been utilized to test the efficacy of some forms of manure which are now becoming important, and experiment is in progress at both stations to test the effect of potash on the potato crop. The analysis of the turnip crop of last year is progressing, but owing to the large scale upon which it is being carried out, and the greatly increased number of the plots under experiment, it will be months before it is completed. A large number of schedules have been sent out to farmers in various parts of the country, describing a simple method of testing the fertility of the soil, and so enabling farmers to discover what manurial ingredients their soils most require. It is a small experiment applied to the turnip crop, costing almost no money and very little trouble, and is capable of yielding information which will enable those who try it to effect some economy in the manuring of their land. The silo at Portmore, whose construction was sanctioned by the society at its last meeting, has now been built. It is made of concrete, and has a capacity of about 170 cubic yards, and it is capable of accommodating about 100 tons of ensilage. The crop to be put into it are of several kinds, viz., about 8 tons clover grass; about 20 tons natural grass, cut from plantations and roadsides; about 12 tons of green oats, partly after lea and partly sown out; about 30 tons of corn and pease, and about 30 tons of tares. These will all be cut and siloed at their greenest, and kept during the winter under a pressure of about 300 lbs. per square foot of surface. In addition to this silo, Mr. Mackenzie is constructing another of slightly larger dimensions to store the produce of 12 acres of natural grass and 8 acres of clover grass, and also a silo on the hill farm consisting of a pit dug in the dry earth, and intended to hold about 10 tons of bog grass. The purpose of these experiments is not only to test the suitability of silos for the preservation of fodder crops grown in this part of the country, but also to furnish information regarding the value of fodder so preserved compared with that of the crops at the time of cutting, and with the same when made into hay. Intimation will be given of the time when the silos are to be filled, so that any members of the society who are interested in the experiment may have an opportunity of witnessing the operation."

The following method of preserving eggs fresh is in use in America:—"I have been in the egg trade for several years, and this is my method of preserving eggs. Take 12 pounds un-slacked lime, 2 pounds salt, 2 ounces cream tartar. Slack the lime in a tub, and then add the other ingredients. Make the solution strong enough to bear up an egg. For family use fill a ten or twelve gallon jar with eggs, be sure there are no cracked ones, and then fill in with the solution and they will keep good and fresh a year."

PARTIES claiming to be posted in sericulture assert that this State can annually produce \$30,000,000 worth of raw silk. This is about twice the amount of gold yield, and it would seem that, as mining gives out, sericulture might be profitably entered upon.—*Sacramento Bee*.

The quantity of Tea per acre in Darjeeling is probably fairly represented in the latest report of the Darjeeling Tea Company (Limited). The figures for five years ranged from 318lb. per acre to 369, so that the average is about 350lb. Now, if estates between 3,000 and 5,000 feet altitude give 350lb. per acre in 27° north, there will be nothing wonderful in an average of 500lbs. per acre at similar altitudes in Ceylon, but 20° nearer to the equator, and with the always more genial climate of an island.

A HEALTHY condition of the Canadian finances is reported. The revenue for the eleven months for the current fiscal year ending with May amounted to \$32,330,103, and the expenditure to \$24,109,926, leaving a surplus of over \$8,000,000, or 1,600,000l.—that is to say, a sum of 1l. for every three inhabitants.

A LARGELY attended conference of representatives of Municipal bodies and Mining Boards was held at Melbourne on the 5th June 1883, to devise measures for the conservation of State forests. Several members of Parliament also attended. It was admitted on all hands that the management of the forests by the Government has been shameful, and that timber has been wasted in a wholesale manner without regard to future requirements. The conference considered that it was incumbent on local bodies and others directly interested to obtain control of the forests within their respective boundaries, and decided that a deputation should wait on the Minister of Lands to-morrow to urge that the forests should be vested in Boards consisting of representatives of the Mining Boards and municipalities within the respective districts, who should be empowered to impose such restrictions as are necessary on the felling of timber, carry on the work of planting and thinning where necessary, and generally undertake the management of such reserves. It was also suggested that the forest be let by the Government for grazing purposes, and a portion of the proceeds handed to the proposed Boards.

DR. SALMON, who has investigated the subject of chicken cholera for the Chicago Department of Agriculture, its cause and prevention, gives the following on the subject of disinfecting poultry-houses in which the disease has appeared:

"For this disease a very cheap and most effective disinfectant is a solution made by adding three pounds of sulphuric acid to forty gallons of water (or one-fourth pound sulphuric acid to three and a-half gallons of water), and mixing evenly by agitating or stirring. This may be applied to small surfaces with a small watering pot, or to larger grounds with a barrel mounted on wheels and arranged like a street sprinkler. In disinfecting poultry-houses the manure must be first thoroughly scraped up and removed beyond the reach of the fowls; a slight sprinkling is not sufficient, but the floors, roosts, and grounds must be thoroughly saturated with the solution so that no particle of dust, however small, escapes being wet. It is impossible to thoroughly disinfect if the manure is not removed from the roosting-places. Sulphuric acid is very cheap, costing at retail not more than twenty-five cents a pound, and at wholesale but five or six cents; the barrel of disinfecting solution can, therefore, be made for less than a dollar and

should be thoroughly applied. It must be remembered, too, that sulphuric acid is a dangerous drug to handle, as when undiluted it destroys clothing and cauterizes the flesh wherever it touches."

The plague of rabbits from which our Australian colonies are suffering has led New South Wales to pass a new and more stringent Rabbit Act, the provisions of which do not err on the side of leniency. Henceforth, any person who shall have in his possession any live rabbit, or even shall introduce into the colony from any other colony or place any rabbit scalps, is liable to forfeit and pay for each offence a sum not exceeding £100, or in default of payment, be liable to a term of imprisonment not exceeding six months. Hitherto the rabbit has not been a terror to our American colonies, but according to the last mail from Canada, his increase in the Dominion is occasioning some alarm. The Natural History Society of Toronto has brought the matter before the Commissioner of Agriculture, and demanded the extermination of the rabbits, which a few years ago were imported to Toronto from England. To do this effectively a set of questions has been sent out by the Government, asking for information on the subject, at the same time giving a description of the rabbit of the country and the English rabbit, which alone is to be treated as vermin, and exterminated accordingly.

FROM a paper by P. H. Jacobs in the *American Agriculturist* we quote the following hints:—

An acre can produce \$400 in poultry, and the capital required returned by the poultry in a short time with profit. With a systematic method of cleaning and feeding, more profit, with less labor, can be derived from poultry on one acre of land than from the best regulated dairy under the soiling method. An acre, devoted exclusively to poultry, will return a greater profit, with less cost in labor, than ten acres of wheat or any cereal crop. The poorest and lightest of sandy soils are more suitable for poultry than the best pastures, as they are freer from disease. That yards free from grass, and clean to every corner, are better than grass runs, has been demonstrated; but shade of some kind should be supplied. No poultry-house can be kept absolutely clean without a board floor. In setting hens, the nests should be in warm, dry locations in cold weather, and in cool, moist places in summer. In selecting for breeding purposes, plumage and points of marking should give way to robust constitution, vigor, and activity. Feeding steeped clover hay and linseed meal assist in the formation of the white of eggs, by supplying nitrogenous matter. The houses should be freely ventilated in summer, and warm in winter. All soft food should be freshly mixed. Yellow-legged fowls sell better than those with dark legs. All non-sitters lay pure white eggs. No male should run with over twelve hens—a less number would be better. Eggs from two-year-old hens are preferable for setting purposes. Exercise should be furnished by throwing a small quantity of corn into a bundle of loose straw or hay, for fowls to scratch. Keep a good dust-bath always. Spade up the ground as often as possible. When a rain is threatened, see to the young chicks. Early-hatched pullets are the winter layers. Keep no fowls for beauty, if profit is the object. Use pure-bred males always. Large males bred on small hens produce legginess in chicks, but small males on large hens produce closer bodies and shorter legs. Never use a male with his own offspring. It is a saving of time to let a hen sit, in preference to breaking her, as hens lay but few eggs when deprived of sitting, and go at it in a week or two. Breed your own fowls, and never bring them to your yards from other places. Hens lay as well when not in company with males as when with them, and such eggs keep fresh longer. Young chicks, when feathering, undergo severe natural drain on the system, therefore never omit a meal. Use only the freshest eggs under sitting hens. Hot white-wash, containing carbolic acid, liberally applied, will kill or keep off vermin. The rough scales on fowls' legs are easily removed by a mixture of lard and sulphur, or coal oil. Finally, be as attentive to fowls as to horses, cattle, hogs or sheep, and be in your yard from morning until night.

W. I. CHAMBERLAIN, Secretary of the Ohio State Board of Agriculture, and one of the most reliable and intelligent officials in that line in the country, publishes on the basis of official telegrams received June 7th, the following table, showing percentages of the condition of wheat at that date, compared with June 1, 1882, together with the yield in 1882 and probable yield in 1883, in the twelve principal wheat-growing states of the Union, which last year produced nearly four-fifths of the entire wheat grown in the country.

It is as follows :

| STATES. | Per cent, June 1. | Bushels in 1882. | Probable bushels in 1883. |
|-----------------------|-------------------|------------------|---------------------------|
| Ohio ... | 52 | 45,464,000 | 23,392,000 |
| Indiana ... | 66 | 45,462,000 | 30,005,000 |
| Iowa ... | 86 | 25,487,000 | 21,919,000 |
| Kansas ... | 71 | 33,243,000 | 23,680,000 |

He says: "This gives a probable shortage of nearly 117,000,000 bushels in these twelve states, and makes it probable that the crop of 1883 will be even smaller than that of 1881; at least in proportion to acreage and population; and this will leave less surplus above 'seed and bread' for export."

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The usual Monthly Meeting was held on Wednesday, the 20th June 1883.

W. H. COGSWELL, Esq., President, in the chair.

THE proceedings of the last meeting held on the 19th April were confirmed.

The following gentlemen were elected Ordinary Members:—
H. J. Haynes, Esq., Manager, Jatook Garden, Meleng Estate, Assam.

R. B. Yates, Esq., Deputy Conservator and Harbour Master Calcutta.

A. Campbell, Esq., Assistant Conservator of Forests, Gornkh-pore.

Dr. J. Mullane, Civil Surgeon, Dhubri.

Manager, Moonsee Tea Estate, Darjeeling.

Captain J. G. Morris, Cantonment Magistrate, Sangor, C.P.

W. L. Thomas, Esq., Merchant, Calcutta.

The names of the following gentlemen were submitted as desirous of joining the Society:—

G. E. Manisty, Esq., C.S., Magistrate, Cuttack,—proposed by the President, seconded by Mr. J. E. MacLachlan.

Edward Bigge, Esq., Merchant, Calcutta,—proposed by W. H. Cogswell, Esq., seconded by Mr. R. Blechynden.

Baboo Ishar Prosad Gorga, of Molsadal palace,—proposed by Raja Sutyayundo Ghosal, Bahadoor, seconded by Baboo Jaikissen Mookerjee.

E. W. Read, Esq., Manager, Latakoojan Garden, Assam,—proposed by Mr. R. Blechynden, seconded by Mr. J. E. MacLachlan.

Baboo Shrochhand Nahar, Asimgunge,—proposed by Baboo Jaikissen Mookerjee, seconded by Raja Sutyayundo Ghosal, Bahadoor.

Edward J. Lawder, Esq., Private Secretary to the Nawab Vikar-ul-Umra, Hyderabad, Deccan,—proposed by Mr. G. L. Kemp, seconded by the President.

J. D. Maxwell, Esq., Merchant, Calcutta,—proposed by W. H. Cogswell, Esq., seconded by G. L. Kemp, Esq.

C. A. Samuels, Esq., C.S., Magistrate, Bancoora,—proposed by Baboo Pertab Narain Singh, seconded by Raja Sutyayundo Ghosal, Bahadoor.

W. Bleck, Esq., Imperial German Consul, Calcutta,—proposed by W. H. Cogswell, Esq., seconded by E. Delfus, Esq.

R. Deey Spodding, Esq., C. S., Collector, Moradabad, N.-W.P.,—proposed by Raja Sutyayundo Ghosal, Bahadoor, seconded by Baboo Jaikissen Mookerjee.

The Nawab Vikar-ul-Umra, Hyderabad, Deccan,—proposed by Dr. King, seconded by the President.

C. A. Sopplitt, Esq., Assistant Superintendent of Police, Cachar,—proposed by W. Atchison, Esq., seconded by Baboo Jaikissen Mookerjee.

R. Blechynden, Esq., Jr., Calcutta,—proposed by Mr. R. Blechynden, seconded by Mr. J. E. MacLachlan.

Re-joined—A. L. Keith Murray, Esq., Manager, Borpane Tea Estate, Nowgong, Assam.

Chas. L. Ambler, Esq., Monghyr.

CONTRIBUTIONS.

A selection of seeds from Trinidad, West Indies. Presented by Dr. J. B. Menzies.

A quantity of Mahogany seed. From Baboo Prosonnocomar Banerjee.

A packet of Broussonetia papyrifera (paper mulberry). From Dr. King.

A large quantity of acclimated maize seed. From the Maharaja of Darbhanga.

A bottle of green sorrel seed. From Mr. J. Stalkart.

A warden case of plants from Mr. E. Koek, of Singapore. (The Secretary was directed to send a suitable selection of plants in the return case.)

A large number of Mahogany seeds from Trinidad. No advice had yet been received regarding these seeds, but they were sown immediately on receipt, Mahogany seeds being so extremely liable to deterioration.

The annual report of administration of the Customs Department in Bengal. From J. Scobell Armstrong, Esq., C.S., Collector of Customs.

Two copies of the Implement and Machinery Review. From the Publisher, H. Westcott, 23, Budge-row, London.

The Manual of Agriculture for India, by Lieut. F. Pognon. By the author.

Department of Agriculture Report for the year 1880. Presented by the Smithsonian Institution.

Proceedings of the Boston Society of Natural History, part of Vol. XX, and 3 parts of Vol. XXI. From the Smithsonian Institution.

The Indian Forester, No. 5, Vol. IX. From the Editor.

Journal of the Asiatic Society of Bengal, Part 1, No. I of 1883, Vol. LII, and Proceedings for February and March. From the Society.

Systematic Census of Australian Plants, Part 1, Vasculares, by Baron Ferdinand von Mueller K.C., M.G., M.D., &c. &c. From the author.

The Tropical Agriculturist for April and May, (two copies each). From the Editor.

Memoirs of the Boston Society of Natural History, Vol. III, Nos. 4 and 5. From the Society.

Report of the Alipore Reformatory School for the year 1882. From the Superintendent.

Report of the Calcutta Court of Small Causes for the year 1882.

Proceedings of the Agri-Horticultural Society of Bijnour, From the Secretary.

Proceedings of the Agri-Horticultural Society of Madras—Annual Meeting and Ordinary Committee Meeting. From the Secretary.

The Secretary was directed to acknowledge all the above contributions, and tender the thanks of the Society to the donors.

COMMUNICATIONS.

Letters, enquiries, and communications on various subjects were read.

From Mr. J. Horne, of the Botanical Gardens, Mauritius, to say a warden case of selected sugar-cane including "Desiderata," would shortly be sent.

Major D. G. Pitcher, of the Agricultural Department, N.-W.P., for a mound of Carolina paddy seed. (To be supplied on arrival from America.)

Mr. E. H. Boileau, Forest Department, Masulipatam, asking for seed of the Rain-Tree (*Pithecolobium saman*). Application complied with.

Chas. P. W. Martin, Esq., Tezpur, Assam, promising a further supply of cane seed from the Duffa Hills.

C. Caspers, Esq., Sub-Divisional Officer, Sasseram, enquiring if the Society can procure seed potatoes for experimental planting in certain Government Mehals. (A reply in the affirmative was sent to Mr. Caspers, who was asked to make an application when the season for planting potatoes approaches.)

In connection with this subject, Baboo Jaikissen Mookerjee promised a supply of potato seed, a very favorable report having been made on samples submitted by him at one of the Society's meetings.

A letter from J. Binning and Co., enquiring for details of working of the Mexican Aloe Fibre Machine, alluded to in the Proceedings of the 21st March last. All the trials up to date not having proved satisfactory, a report is withheld pending further trial.

MOORAH SILK.

The following letters on this subject were read:—

J. W. Holderness, Esq., *Simla*, 26th April 1883.—I am directed to forward a copy of a letter from the Political Agent at Baghdad, and its accompaniment, together with the sample of the fibre therein alluded to, and to say that this Department would be glad to be favoured with any information available that would lead to the identification of the plant which yields the fibre in question.

W. Tweedie, Esq., *Bagdad*, 30th January 1883.—I enclose copy, with English translation, of a letter in Turkish, just addressed to me by his Excellency Muhammad Hidayat, the Mushir Pasha, or Commander-in-Chief of this Wilayat, asking for a supply of a seed which, as far as can be made out, is that of the fibre from which, in India, the fabric known as Moorah silk is made.

From his Excellency Muhammad Hidayat Pasha, to H.B. M's Officiating Consul-General, Baghdad, dated Baghdad, 29th January 1883.

"Translation.—It is understood that a fibre called in this country Shaari, believed to be a species of *Sax* which is much used in embroidery, is produced abundantly in India.

"My idea is that the rich soil of this Wilayat would easily produce the article in question if the seed were introduced, which

would be the rendering of a service only to be expected from the interest you show in matters of public benefit; and if you will permit me in taking this opportunity of expressing my friendship and regard, to ask you to apply to the Government of India for a supply of the seed in question, I shall esteem it a favor."

The following report was furnished by the President:—
It is a difficult thing at all times to form any thing like a reliable opinion on such a very small sample of fibre as the one now referred to, and to be able to state with any degree of accuracy what it really is, or to identify the plant from which the fibre has been produced.

My first impression was that it might be the *Sansaviera Zeylanica*, the moorga fibre *Sans murva* or *Beng. Moorga* and *Moorgayee*, described by Sir Wm. Jones in his *Asiatic Researches*; the leaves of which plant I send herewith. The same fibre is referred to by Dr. Roxburgh, Dr. Forbes Royle, and others in their several works on Indian Fibrous Plants, as used for ropes, lines, bow strings and producing a soft fine fibre, resembling silk, and capable of being spun and manufactured into cloth.

On comparing the sample, however, with the Moorgah or Moonga *Saccharum*, Munga Silk Fibre, some specimens of which from Assam are in the Society's Museum, presented 42 years ago, and with a sample kindly placed at the Society's disposal by Dr. McCann, Officiating Secretary of the Economic Museum, they correspond so exactly with the above-named Persian sample that I think they are identical. Dr. McCann also drew reference to Balfour's *Encyclopædia*, in which work this silk fibre is spoken of as having been mixed with cotton and manufactured into a fabric at Dacca, which was largely exported to Jeddah and Bussorah, and it may be to this that his Excellency Muhamed Hidayat Paasha refers in his letter to the Political Agent at Baghdad.

W. H. COGSWELL.

The Deputy Secretary intimated that an acknowledgment of the above report had been received from Mr. Holderness, Offg. Under-Secretary to the Government of India, who had mentioned that specimens of the fibre are being procured from the places mentioned in Mr. Cogswell's note.

A NEW TEA INSECT.

Messrs. Begg, Dunlop and Co. write:—

"In continuation of previous correspondence, we have now the pleasure to hand you per bearer a tin, containing a number of the insects received from the Lung Ling estate, the manager of which wrote us as follows:—

"I am packing up for despatch to you a large quantity of the new tea insects in two of their different states. I cannot obtain the moth. I hardly think it is time for it yet."

The insects were forwarded to Dr. Anderson, of the Indian Museum, who had kindly consented to observe their habits, and who had procured a supply of food suitable for them from Dr. King; any further communication received on the subject will be published in due course.

The attention of the members present was drawn to some very large specimens of tea leaf from the Dooars forwarded by Mr. F. F. Wyman, editor of the *Tea Gazette*. In reply to an enquiry as to whether the bushes from which the specimen had been taken were treated in any special manner, Mr. Wyman forwarded the subjoined communication from his correspondent:—

I send you specimens of tea leaves of this season's growth from the Western Dooars. Several you will see are exceptionally large for the first three leaved and the bud, and will give great weight of tea.

"*Bagracote, 18th May 1883.*—Your favour of the 8th instant to hand, I am glad to hear you have received the tea leaves and shoots safely. The leaves and shoots represent the average of the major portion of this garden.

"A portion of the tea is eight, rising nine years, and a portion seven, rising eight years. We have several other blocks just as good, and few blocks of pure indigenous and extra good hybrid much better. As the latter are, however, young bushes, and at the further end of the garden I did not pluck any samples from them. I could, I think, send you leaves nine and ten inches long. As the bushes, though young, are very fine for their age, no part of this garden has ever been manured, nor have any of the blocks received any special treatment. The growth in the Dooars is really most astonishing. I have never seen such rapid growth in Assam."

Mr. Wyman also forwarded some leaves for identification.

"I send you also some leaves of a plant very much like those of the tea plant, for which they are often mistaken."

Dr. King kindly identified the leaves as those of the *Eurya*. He remarks, has frequently been mistaken for tea. The Deputy Secretary mentioned that he had some years ago seen some "tea" made from the leaf in question which had all the appearance of the genuine article.

RHEA, OR CHINA GRAIN SEED.

A letter from Mr. Bleock, Imperial German Consul, was read:—

"I have been requested to procure some pounds of good sound seed of the *Rheum* (nettle) plant.

"Several Agricultural Societies in Germany have vainly tried to procure good healthy plants from seed obtained from France; and are now desirous to make an experiment with the real Indian seed."

"I therefore venture to ask whether you will be kind enough to procure the said seed for me, or if this be impossible, would you please inform me where it can be got?"

The Secretary mentioned that the seed was difficult to procure, as it is seldom preserved owing to the fact of the plants being much more readily and readily propagated from cuttings and divisions of roots, and that he was informed by the Superintendent

of the Government Botanical Gardens, Saharanpore, that it did not seed there at all, the plant being of one sex, though he had once raised Rhea from seed procured from Java. Efforts are being made to obtain the seed to meet this and other similar applications.

WHEAT AND COTTON.

Samples of these were sent by the Superintendent, Agri-Horticultural Society's Garden, Lahore, on which the following report was given:—

"*Cotton.*—This sample of Kuppas, that is, with the seed left in uncleaned, is most beautiful, the staple is soft, silky, long, strong, and of a clean, white color. It would sell most readily in the Home markets if the seed was separated from the fibre, and would realise high prices, as compared with the American cottons. It would have to be sent to Europe, for the quality is far too good for the local mills in India, whose spinners are almost entirely on low counts of yarn. It would be interesting to see a sample of this cotton after the seed had been separated from it.

"*Wheat.*—The samples marked C 1, 2, and 3 are not sufficiently marked in character to separate, so must be taken as a whole. They would rank with *Allyghur* wheat worth about Rs. 2-14 a maund. The grain is good, bold, and plump, but not so good in color as *Mearat* wheat, the latter being whiter, whilst the former is yellow, and worth about Rs. 2-15. The samples marked L G 1, 2, 3, like the former are not sufficiently marked in character to separate, so I treat them as one sample. The wheat is damaged and spotted, with much grain discolored, and would not sell for shipment hence in consequence, but would be bought only by the local retail dealers. It is worth about Rs. 2-8 a maund.

"W. H. COGSWELL."

GARDEN.

There is nothing very particular to record under this head; steady progress has been made with the work indicated as more urgent by the Garden Committee. The remains of a shed near the dwelling-house has been removed, roads rolled and weeded. The gaps in the wall have been rebuilt, and levelling the lawn taken in hand. The propagator, whose appointment was confirmed at the last meeting, has been doing good and satisfactory work, and has now a large stock of roses which should be ready for distribution at the usual time at the end of the rains.

The new sorts of *Achimenes* got out last year are looking strong and healthy. The attention of members is drawn to the large stock of mahogany plants now in hand, upwards of 1,000 being ready for immediate distribution. There are also a large number, about 1,000 seedlings, of Arabian coffee available, some young Indian rubber plants, a few teak, divi-divi, and a large stock of fruit grafts, mangoes, lichees, and peach, &c. A potting shed for use during the rains is in course of erection from materials, most of which are available in the Garden, so the expense will be trifling. Since the last Meeting the garden has been visited by a severe storm which snapped off some twenty feet from the top of the fine young *Eucalyptus* tree south of the lawn, and uprooted one or two other trees, but no great damage has been done. There have not been many cash sales as usual during the hot, dry season. The new orchid-house is well filled with plants, and a large quantity of finely screened ashes were obtained and laid down, giving a firm, dry, and pleasant flooring. An experimental sowing of early Amber Sugarcane (the seed of which was presented by Captain Pogson, and noticed at the last meeting) resulted in a failure, only a few seeds having germinated. A great quantity of brick rubbish has been collected from various parts of the garden, as it rendered digging, &c., difficult, and was very unsightly. Arrangements are being made to sell this as road metal, the proceeds to be used to buy "kunker" for the garden roads; this will be cheaper than making it into material on the garden.

RICE-HUSKING MACHINE.

In the Proceedings of the 27th September 1882, the following allusion was made to a Rice-Husking Machine:—

"A model as used in the West Indies by the Chinese has been constructed by the order of Mr. W. H. Cogswell from a rough sketch kindly furnished by Mr. H. A. Firth, and it has been determined to give the same a practical trial shortly, with a full report thereon, so that its usefulness may be generally made known."

The model is apparently of the full size and stands 2 ft. 9 in. high; it consists of an upright shaft or column of hard wood, the upper face of which is cut into deep grooves radiating from the centre where a strong pin is fixed; the grooves are quarter of an inch in breadth and one-eighth in depth; a heavy disc of hard wood similarly grooved and of the same diameter is made to revolve rapidly, the central pin being the axis; paddy is poured into a receptacle on the top of the revolving disc, and falls out in the form of rice and husk into a circular trap affixed to the shaft. Grain is then separated from the chaff, either with a winnowing machine, or by the very effectual native hand process. In making such a machine for use in India the upright shaft might be dispensed with and a heavy block of wood substituted, so that the top of the revolving disc would be within reach of the manipulator when seated in the only position a native of India seems able to work in. This would also reduce the price somewhat, as the tray, too, could thus be dispensed with, and the rice would be allowed to fall directly on the floor. In whichever way it may be made, the machine is so simple that any common village carpenter could make one at a very trifling cost.

The result of the trial against the "dheki" and upcountry "akhli" is given below. It may be proper to note here that the dheki has one advantage over the rice-husker, viz., that the rice, after being husked and winnowed, can be recombined; and the brown marks which will always be found on rice thus removed; this process whitens the grain and brightens it considerably,

making a difference of some three or four seers in the rupee in the marketable value. It is, however, to be remarked that should this be considered necessary, the rice can be put under the dhaki after being husked in the machine, at a great saving of time and cost. It need scarcely be said that the whitening process involves a loss in weight.

The machine has a marked advantage over the primitive native methods when "arooah" or unboiled paddy is dealt with, as the difference in breakage, as noted below, is then very appreciable, and when it is remembered that a great number of up-country natives object to "usna" rice (made from boiled paddy) its advantage over the dhaki and ukhli in this one respect alone should make it sought after, leaving out of consideration its other advantages which a glance at the table given below will show. It is of course for consumers to decide which rice they prefer, but arooah (unboiled paddy) rice would seem a somewhat more cleanly article than usna (boiled paddy) rice boiled with water, to the quality of which the majority of consumers are as a rule profoundly indifferent.

RESULTS OF TRIALS.

| | No. of men. | Time (minutes.) | BOILED PADDY, "USNA." | | | | % Broken Rice. |
|-------------|-------------|-----------------|---------------------------|--------|--------|--------|----------------|
| | | | Paddy. | Rice. | Husk. | Waste. | |
| | | | Seers. | Seers. | Seers. | Cht. | |
| Rice Husker | 1 | 17 | 5 | 3-12 | 1-1 | 3 | 18½ |
| "Dhaki" | 2 | 38 | 5 | 3-10 | 1-2 | 4 | 81½ |
| "Ukhli" | 2 | 22 | 5 | 3-8 | 1-2 | 6 | 81½ |
| | No. of men. | Time (minutes.) | UNBOILED PADDY, "AROOAH." | | | | % Broken Rice. |
| | | | Paddy. | Rice. | Husk. | Waste. | |
| | | | Seers. | Seers. | Seers. | Cht. | |
| Rice Husker | 1 | 17 | 5 | 3-10 | 1-3½ | 2½ | 37½ |
| "Dhaki" | 2 | 24 | 5 | 3-6 | 1-5 | 5 | 93½ |
| "Ukhli" | 2 | 25 | 5 | 3-10 | 1-2 | 4 | 31½ |

In the above table the column "broken" includes all rice however slightly broken or even chipped, hence the very high percentage.

OFFICIAL PAPERS.

AGRICULTURAL EXPERIMENTS CONDUCTED BY PUNDIT AJUDHIA PRASHAD.

From PUNDIT AJUDHIA PRASHAD, Illaquahdar, Indalporo, and Shahjahanporo.—To W. C. BENNETT, Esq., Director, Department of Agriculture and Commerce, N. W. P., and Oudh, Cawnpore,—dated Indalporo, the 15th of June 1883.

SIR,—1. In forwarding to you a report of the agricultural operations carried on by me during the year 1882 and 1883, I shall not trouble you with a minute account of the procedure which is pretty much the same from year to year, but I shall confine myself only to such particulars as are, owing either to their novelty or importance, specially deserving of interest and attention.

2. About the *khari* crops therefore I have not to notice much, saying that I tried a peculiar sort of *wad* called *sarabha*, in fields that had received deep ploughing. The resulting outturn was exceedingly good, and the *wad* produced carried the first prize at the Golagokuru exhibition.

3. My *urug*, too, this year was of an unusually superior sort, and on samples thereof the first prize at the aforesaid exhibition was awarded.

4. *Rabi*.—In my report last year I gave a table showing that the outturn yielded by the Mousserporo soft white wheat was better than that given by the other kinds sown here. Emboldened by this feature of the experiment I tried the soft white variety very extensively in the season under report, sowing it over 93 beeghas in all my five farms. The outturn fully supports the conclusions I had previously arrived at. An exceedingly satisfactory result of this extensive experiment is, that the zemindars of the neighbouring villages and the *asamees* generally have come to understand that the cultivation of the soft white wheat is more remunerative than that of the ordinary kinds. Accordingly I have been requested by many people to supply them with seed, and I doubt not but next year I will find the cultivation of this variety more extensive and general.

5. I am also now in a position to state my opinion as to the utility of picking the seed before sowing it. All the soft white wheat seed that was sown at Indalporo (Farm No. 1,) last year was carefully cleaned and picked before it was taken to the field. The fields sown with the seed so treated, beat the other fields sown with the same sort of wheat without the special treatment. In

those sown with the picked seed the produce was fully double that given by the fields in which the ordinary *katha* wheat was sown. Not only was the outturn larger in quantity but it was also better in quality. The grain produced by the picked seed is larger, whiter, and better flavored than that produced by the ordinary method of sowing. So far as this experiment goes, I can confidently state that picking and cleaning the seed before sowing is one of the essentials that result in the production of large outturns of extra superior quality.

Seed supplied by the Department of Agriculture and Commerce.

6. *Cape Oats*.—I tried the five seers of Cape oat seed that was supplied by your department. The produce equals that of the country barley, but the grain produced is inferior. It is also with the greatest difficulty possible to grind the oats by the ordinary flour mills (*chakkars*) and hence it would not do to cultivate this variety as a food crop. No doubt it would be very good as fodder, but then fodder artificially cultivated is not a desideratum in these parts, because the jungle and plains bordering upon the villages are full of the most luxuriant grass which supplies the cattle all the year round with food. It is my opinion therefore that the cultivation of these oats can never be universally adopted here.

7. *Guinea Grass*.—I tried it in the valley of the river Goomtee as proposed last year. The shoots came up very well, were healthy and promising, but the sudden overflow of the river submerged and killed them. I cannot therefore confidently state whether the grass will succeed here. I will nevertheless try once with the proper precautions, and hope to be able to give my opinion about it after the next trial.

8. *Maizes*.—Of American maizes I received five varieties from your department in 1881. I tried them year after year as *khari* crops. I did not, I am sorry to say, succeed at all in the experiments. Few cobs ever came to maturity, and those that did, bore very inferior and degenerated grain. I however persisted in sowing the deteriorated grain simply to save a little seed. In these repeated trials of mine the seeds of the different varieties got mixed, and I ultimately found that on gathering the cobs, some were produced that differed from the original seed in shape, color, &c. While trying to account for the appearance of these new varieties, it suddenly struck me that perhaps when flowering the plants of different varieties had fertilised each other and had thus produced new hybrids. Meanwhile at the beginning of the season under report your department sent me two varieties of American maizes, namely, white flint corn and yellow Capada corn, for trial as winter crops. I suddenly thought of trying my own deteriorated seed along with the new one as a winter crop, and wishing at the same time to test the fertilisation theory that I had previously arrived at. I followed a peculiar plan in the cultivation. I sowed the seed obtained from your department in long lines, and on either side of those lines I sowed my own deteriorated seed. Owing to the proximity of the different varieties one to another, I thought that fertilisation would be helped a great deal, and when the plants flowered, I shook them in all directions. The result was that when the crop ripened and the cobs were gathered, many new varieties were found; some of these possessed exceedingly beautiful and characteristic colors. The experiment on the whole was a thorough success, the grain produced being superior to the original seed sent to the Golagokuru exhibition, and all the gentlemen that saw them there were surprised at the largeness of the grain. I intend next year to sow each cob that exhibits a peculiarity in shape or color separately by itself, and will then report the result of the trial.

9. *Sugar-cane*.—I reported last year the new system that I had adopted in dealing with tenants, namely, that of purchasing cane from them, and crushing it for myself instead of buying ready pressed juice. The success that I had last year induced me to extend operations in the season under report, and I accordingly started two *rab* factories. One as usual worked at Indalporo, and the second was opened at Januri, a village of mine near Tilhar. The system of selling cane is gradually getting into favor with the *asamees*; they are, as is well known, averse to innovation and are very chary of adopting things unless they are thoroughly satisfied of the profit likely to result. Gradually they are learning to appreciate the system of selling cane.

10. Repeated experience in cane cultivation has taught me a thing which would benefit those that try sugar-cane. The plant is propagated by cuttings which are of two sorts—*lat*, Khundwan, and 2nd, *Agraha*. The first is obtained by taking the clean cane, and chopping it up into portions about a foot long. These bits are placed in the field and give off-shoots. On the second system the whole of the cane is not utilised for cuttings, but the crown top alone is taken, and that is placed a few inches below the soil in the prepared field. Now although both these systems are followed, my experience causes me to prefer the second sort of cutting, as because it is tender, it germinates very soon and also gives off a very large number of shoots. On the other hand the Khundwan sort are very tough, and as they are full of sweet juice, are in great danger of attack from white ants. It is therefore advisable to use the *Agraha* or crown top cuttings as far as possible and to avoid using the Khundwan ones.

11. I must also in this connection note the fact that deep ploughing does enormous good to sugarcane as well as to other crops in general. I stated this fact in my reports of past years, but I now do so again as year after year my belief in its efficacy gains greater strength. One good feature and a rather important one is that sugar-cane grown on deeply ploughed land withstands drought more than that grown on lands that are not deeply ploughed. Besides, all this deep ploughing does not only give greater outturn, but permanently improves the land. A remarkable instance of this result of deep ploughing is seen in one of my villages called Hetinanagra. During the past years owing to a variety of causes the *asamees* gave up cultivating a large area of land in that village and this put me to great loss. I some years ago

opened a farm there and cultivated almost all of this land for myself. I used the improved ploughs and thus all the fields in time began to grow. *Asamies* now think the fields to be very good, *want them back; they are even willing to pay larger rent.* All improvement in the land I can only attribute to the introduction of systematic farming.

Process of making Sugar from Rab.

12. I stated the *bel* process of making *rab* last year, and I would now like to give a short description of the method by which *rab* is made into sugar. The process is divided into 2 parts. The *Khurees* or clay pots full of the *rab* are taken to the *Khundisar*, and two or more workmen take charge of them. There is an oblong structure with walls about a yard high called *channee* the interior of which is lined with a blanket, before which the workmen stand. Each of them lays hold of one pot, lifts it up, and places it on the wall of the *channee* and then by means of the thick handle of a little *Khurpes* knocks off the upper half of the pot. Then by means of the flat *Khurpes* he scrapes and throws the *rab* into the *channee*. This operation is conducted until it is thought that an amount of *rab* sufficient for the day's work has been thrown into the *channee*. Through the blanket which lines the interior of the structure, a part of the molasses of the *rab* filters and passes by a drain into the hole intended to receive it, represented at the left of the figure. Each workman is then provided with 12 bags made of coarse blanket stuff into which he fills the *rab* from the *channee* and ties the mouth with bits of rope. These he arranges in a vertical pile on a structure known as the *Khurea* in the drawing, and then places a heavy cylindrical block of mud on the top of all. Straight rods of bamboo (about 1½ inch thick and 1 yard in length) are attached to the pile of bags to keep it steady, and then the workman mounts on to the top of the pile supporting himself on a cross beam represented in the figure, and shakes the pile backwards and forwards and pressing with all his might on to it. Owing to this pressure the molasses flow out of the bags and fall to the bottom of the *Khurea* whence by a drain they pass into the *mund*, a pit well plastered with mud and *dhua* which is constructed near at hand to receive them. If the *rab* is tolerably good, it is thus manipulated for about six hours, after which the bags are removed from the *Khurea*, opened, shaken about, and re-arranged in the self-same way. The pressing again commences and is carried on till the evening when the pile is left, for the night. In the morning the bags are opened and the *rab* with which they were originally filled is by this time converted into *putree*.

The second part of the process then comes into play. In a small room, an oblong enclosure is made by means of thatching straw *tattees*. Bricks are arranged on the floor of this enclosure and then a thick covering of reeds (*sethas*) is laid on them. A cloth called *pullea* is then spread over the whole, and then the *khanchee*, as it is termed, is ready to receive the *putree*. The *khanchee* is filled with *putree* and its upper surface is smoothed. A thick layer of (*shear*) river weeds, is then spread on the top, and this is allowed to remain for a few days. The *shear* is then removed and to a certain depth—an inch or so, the *putree* is found to have turned perfectly white. This portion is scraped off by means of iron instruments called *kurchulus*. To the newly exposed surface another covering of *shear* is applied and from day to day the application of the weeds and the scraping are carried on alternately. This scraped sugar termed *pucknee* is spread on a piece of coarse canvas (*patia*) which is placed in some place exposed to the sun, and a few laborers tread over it and rub it with their feet. This operation dries the sugar and makes it white, and thus is formed what is termed *khand*. In this form the sugar manufacturer sells his produce. When required for use, this *khand* is made into syrup which is boiled and clarified by the addition of milk and *ghee*, and is then allowed to thicken, care being taken to prevent crystallisation by rubbing and beating it with wooden instruments, shaped like thick spades. It then gets the name of *chini* or *bura*.

13. There are a few by-products that need notice. After the *pucknee* is scraped off the *khanchee*, the surface of the latter is carefully broomed and little bits of the weeds steeped in sugar are gathered. These are accumulated and when sufficient in quantity are soaked in water and the syrup thus obtained is boiled. It thickens to the consistence of *rab*, and has a peculiar flavor. It is generally reserved by the manufacturer for home use, and goes by the name of *chota rab*.

14. When the *khanchee* is emptied the reeds that were laid at the bottom are found covered with thick white crystals of sugar termed *payrk*. These are generally consumed by the manufacturer himself.

15. The cloth *pullea*, the reeds and the bricks laid at the bottom of the *khanchee* are then washed in water, and the solution is then boiled and converted into little oblong cakes of sugar termed *kutree*.

16. The molasses that flow out of the *khanchee* are of two sorts. When the *khanchee* is first filled with *putree* for a few days a thick sort of molasses flows out; this is called *kutocha* and is sold along with the ordinary *sheera*. After a few days the molasses becomes thinner, and then gets the name *garab*. This on being boiled is converted into a thick sort of inferior *rab*, which, on being subjected to the process of clearing and filtering above described, yields a sort of inferior sugar.

Implements.

17. *Boiling Pans*.—In my report last year I noticed the many shortcomings of the rude iron pans used for boiling sugarcane juice, and I also stated that at the suggestion of Captain Clibborn I applied for cast-iron pans from your department. You were pleased to suggest that I would be a loser if I used cast-iron pans, because in the course of a few years the iron would oxidise, and

would then be comparatively of little or no value. You at the same time thought that copper would be a better material to use. Five copper boilers were accordingly made under the supervision of your department, and I used them in making *rab* last year. The result of the experiment is exceedingly gratifying. The *rab* produced contains a less amount of molasses than it used to do, and at the same time is better in grain and color. This superiority I can only attribute to the use of these pans, as owing to them, heating of the juice was more equal and steady, and all the application of the bell fruit, *uri* flower, &c, things that disfigured the *rab*, was avoided. Many people came to see the pans working, a greater part of them were sugar-growers and they all agreed as to the usefulness of these pans. At the Golagokura Exhibition I saw an American sugar-boiler that was exhibited by Major Pitcher. The apparatus was exceedingly economical and efficient, and I doubt not but that it would be of great service here. If it were possible to obtain a few such boilers manufactured at your workshop, I would be exceedingly glad to obtain four or five of them, wherewith to extend operations next year. If they cannot be had, I will be obliged to be under the necessity of applying to you for another set of copper pans like those which Major Pitcher so very kindly constructed for me last year. It is impossible for me to get them done here, and I will not like, after using pans of this and the better sort, to revert to the rude country ones, so that I will be obliged to trouble you for another set.

18. *Martin Ploughs*.—Two ploughs of this sort were very kindly supplied to me by Mr. Mulock for trial. I have used them, and find them to be very light and cheap. The ordinary cultivators like them very much as they can be worked by common bullocks. They were made at Shahjahanpore and cost Rs. 2, annas 4 each, which is really very cheap, and places them within the reach of almost every one.

19. *Dehea Sugar Mills*.—I have continually been trying these mills and worked twelve of them last year. The contemplated extension of work will, I hope, necessitate my buying a few more. I consider it now needless for me to state that I am thoroughly satisfied with these mills, as I think their superiority has now been very well established.

20. *Threshing*.—Repeatedly I have found the absence of a proper apparatus for threshing corn, one of the most injurious and troublesome difficulties that besets one who attempts agriculture on a large scale in these parts. A man spends a lot of money on his fields, goes to the trouble of watching, irrigating, and otherwise looking after them, mows his crops, and thinks that he is now about to realise the fruits of his labor. All of a sudden falls a shower, the *dhua* rots and becomes worthless, and hundreds of maunds of grain is spoiled. This state of things is exceedingly painful. I met with severe losses in this way in the last *rabi* season. I, and I may safely say all those that try agriculture largely, would be exceedingly grateful could some remedy be suggested. An efficient threshing machine is a desideratum the want of which is very painfully felt. At the Golagokura exhibition I saw a machine called the Indian corn-shelling machine. I am of opinion that it could with some modification suit the purpose of cleaning *Bajra* very well and would then be exceedingly useful in these parts, as *Bajra* is one of the principal staples grown here in the *Kharif* season.

21. *Cattle*.—With regard to the Canwarea bull I have to state that it is doing very well. During last year I had sixteen calves in all from him, and there are 30 more in the village. They are very beautiful and promising, and there is every prospect of their maturing into fine cows and bulls. I think that the plan I followed of allowing the bull to run and remain unrestrained along with the *klu* is very successful.

22. *Donkey Stallion*.—The stallion remained with me for more than a year—but the climate for this place did not seem to agree with it, so that I was ultimately obliged to send it back to the stud department. There are one or two young mules here, but the people it appears do not care to breed mules.

23. *Salotri*.—In July 1882, I wrote to you telling you of the fearful mortality that then prevailed among cattle here. You made my letter over to Major Pitcher who very kindly sent me a salotri that reached me in September 1882. He treated 387 cattle in all, out of which he was successful in 347 cases. In 29 cases he failed, and the cattle died, and of 11 cases the result was unknown. I must say that with regard to the treatment of wounds and in surgery generally, he was exceedingly successful, but I am sorry I cannot say equally well of his treatment of the disease for which he was specially sent for. I do not know the technical name of the distemper, but when afflicted with it, the animal suddenly becomes unable to move, is purged fearfully, and continually vomits greenish water. The salotri called this disease cattle-pox, and although successful in one or two isolated cases, signally failed in doing real good. The natives called this disease *rej*.

24. In connection with cattle and their diseases, I must notice the thorough and complete success that resulted in almost every case in which I experimented with Jeyo's Purifier. This medicine acts wonderfully on the wounds and sores of cattle, and cures them in almost no time. It destroys vermin instantaneously, and was of great use to me in my sugar factories, where it promptly destroyed the big black ants that attack sugar in myriads and do lots of injury. I found it equally successful in healing the wounds and boils of men.

25. *Mulberry Cuttings*.—Thinking that the sandy nature of the soil here was suited to a growth of mulberry, I applied to the Superintendent of the Botanical Gardens, Shahjahanpore, who sent me 300 mulberry cuttings. I planted them and they are thriving. I will transplant them to the river side in the ensuing rainy season. Ultimately, I intend starting some experiments in sericulture.

26. In conclusion, I must offer my sincere and heartfelt thanks for the ready assistance and kind advice that I have always received from yourself and Major Pitcher.

I have the honor to be,
Sir,
Your most obedient Servant,
AJUDHIA PRASHAD,
Illaquahdar of Indalpoore, &c.,
District Shahjahanpoore.

MR. SABAPATHY MOODELLIAR'S AGRICULTURE EXPERIMENTS.

THE following is a report from Mr. W. R. Robertson, M.R.A.C., Agricultural Reporter to the Government of Madras, to the Director of Revenue Settlement and Agriculture, Madras, dated Saidapet, 23rd January 1883 :—

"In the early part of last month, I availed myself of the permission granted me in the Proceedings of the Board, dated the 9th October last, to visit Bellary and inspect the agricultural operations conducted there by Messrs. A. Sabapathy Moodelliar and Co., and I have now the honour to submit my report on that inspection. Messrs. A. Sabapathy Moodelliar and Co.'s operations have extended over a wide area of country. In 1881, the area worked by the ploughs they had introduced was 1,900 acres situated in 10 different villages; while, last year, the area was increased to 3,430 acres situated in 17 different villages. Opportunities have thus been afforded to a large number of ryots for witnessing these important experiments, as the villages in which the experiments were conducted are scattered over a tract of country fully 30 miles wide. The portions of this land that I inspected are situated near Hagari and near Bantanahal. In my inspection of the land at the former place, I was accompanied by the Collector of the district, and we were conducted over the land by Mr. A. Sabapathy Moodelliar, Mr. Sabapathy Iyer, and Mr. Firth. In inspecting the land at Bantanahal, I also had the benefit of the company of Messrs. Sabapathy Moodelliar and Firth. Before proceeding further, I must express the very great obligation I feel under to these gentlemen for the trouble they took in accompanying me over the land inspected, and for the full and valuable information they placed at my disposal. I fear (in the great interest I felt in what Mr. Sabapathy Moodelliar had done, and is doing), I somewhat transgressed the bounds of fair inquiry, for it must be remembered that the enterprise is entirely of a private nature; but if I did do so, it was not resented, for not only was all available information fully afforded to my inquiries, but it was given in a way to suggest other and further questions. The chief circumstances which induced Messrs. Sabapathy Moodelliar and Co. to give their attention to the introduction of improved ploughs for working the cotton soils of Bellary having been noticed at length in the General Report of this department for 1881-82, at pages 14-10, it is unnecessary to notice them again here. Messrs. Sabapathy Moodelliar and Co. have, for some time, been largely interested in the cotton trade of the district, and are now extending their operations to spinning and weaving cotton, and are constructing a large mill for these objects in the town of Bellary. A regular and full supply of cotton, of a good quality, is therefore a matter of considerable importance to this enterprising firm—objects quite sufficient to explain Messrs. Sabapathy Moodelliar and Co.'s interest in, and their desire to improve, the husbandry of the district. But, I believe, Mr. Sabapathy Moodelliar is influenced by other objects than mere personal gain, highly laudable as such an object would be. He has long been connected with the district, is familiar with a considerable part of it and the people of the cultivating classes, and has noticed with concern the gradually increasing poverty of the people and the less and less care devoted to the tillage of the soil—influences which, in a season of great drought culminated in the famine, which so recently devastated the district, resulting in a loss of one-third of the population and the abandonment of nearly one-third of the arable area. Mr. Sabapathy Moodelliar has deeply considered this and other circumstances bearing on the state of agriculture in Bellary, and has fully convinced himself that it is the imperative duty of all men possessing wealth, who have any interest whatever in the welfare of the district, to use some of that wealth and what influence they possess in promoting whatever may tend to further the interests of husbandry. Mr. Sabapathy Moodelliar looks upon this duty in the same light as many others of his countrymen who possess wealth do on the duty to provide choultries and similar institutions for Brahmins and other castes, but that the duty to promote the agriculture of the country is of paramount importance—a view in which I venture to believe all will concur who possess any real knowledge of India and its husbandry, and who desire to see the country prosper. Messrs. Sabapathy Moodelliar and Co. have introduced into this district the under-mentioned ploughs :—

| | | | |
|--------------------------------|-----|-----|-----|
| Swedish ploughs | ... | ... | 334 |
| Improved wood and iron ploughs | ... | ... | 60 |
| Ransome's double ploughs | ... | ... | 5 |
| Do. triple furrow do. | ... | ... | 1 |
| Do. four-furrow do. | ... | ... | 1 |
| Total | ... | ... | 401 |

They have already sold 132 of the Swedish ploughs and all of the Ransome's double ploughs. Some of the ploughs were sent to the Nizam's Dominions, the Mysore Provinces, a few to the Kurnool District, and to the Dharwar District in the Bombay Presidency.

Thus the good influences set in operation are extending widely. Judging from the great gatherings of ryots I saw, and the great interest they appeared to evince, at Bantanahal and elsewhere, where the ploughs were exhibited at work, or the land that had been ploughed could be seen, Mr. Sabapathy Moodelliar is apparently doing much good in the district. It was a great pleasure to accompany him over the land, and to witness the interest with which the ryots listened to his remarks, and the apparent pride they took in the superior crops raised on the deeply-ploughed land. I am convinced that the movement is entirely spontaneous on the part of the ryots, and is due simply to their appreciation of the quality of the work done under Mr. Sabapathy Moodelliar. The plough in most request is a Swedish Plough No. 16, which after being strengthened is sold at Rs. 65 each. Though it is, I think, the largest and heaviest plough that has ever been introduced into this part of India, the ryots, in their appreciation of the deep-going power of the plough, sometimes drive it much deeper than it is intended to work, and the consequence has been that in several cases the powerful beam of the plough has been bent; but Messrs. Sabapathy and Co.'s Work-shops have proved equal to this emergency, and the ploughs of the kind now sent out have first their beams strengthened by iron plates. The ploughs are sold to ryots either for payment in cotton, for cash, or on credit for 4 or 8 months. In some cases, the ploughs are lent on hire at Rs. 10 per month. Ploughing to an average depth of from 10 to 12 inches, these improved ploughs are said to do the undermentioned work per day of 8 hours :—

| | | | |
|--------------------------------|-----|-----|-------|
| Land in a very dry state | ... | ... | Acres |
| Land in a moderately dry state | ... | ... | 0½ |
| Land in a very good state | ... | ... | 1 |

Mr. Sabapathy Moodelliar estimates that he can, when the land is in good condition, plough with his large plough, from 10 to 12 inches deep, with 4 pairs of cattle, at a cost of about Rs. 3 per acre, whereas he could not with the large country plough get as good work done for Rs. 8 per acre. I should consider, from what I saw done, that the large country plough would do a shorter length of furrow than one of the improved ploughs, and that one operation of the latter is equal in effect to two of the former. Ploughing a furrow 12 inches wide, an improved plough would have to travel 8 miles to perform one acre of ploughing, but 20 per cent of the time would be lost at the headlands in turning; the useful day's work would therefore be 4.8 hours; the cattle would thus need to travel nearly 2 miles per hour—a much faster speed than usual. I certainly saw some of the ploughs worked at a speed as great, but it was only for a short time, and could not be kept up during a day. Probably, therefore, three-fourths of an acre may be taken as a full day's work with one of the improved ploughs when the land is in really good order. The country plough could not get over more than two-thirds of an acre per day, under similar conditions, and would need to go over the land twice: its effective work would therefore be one-third of an acre per day, and three days would be occupied to do on acre with six pairs of cattle. No bad results have followed one deep-ploughing these black cotton soils, as far as is known; the fact is, that the cotton plant is the chief crop and its deep roots prepare the soil for deep ploughing. Messrs. Sabapathy Moodelliar and Co. have ample facilities for repairing iron ploughs at their Cotton Presses, of which they have eight in different parts of the district. They trust to be able to make iron ploughs ere long. Much of Messrs. Sabapathy Moodelliar and Co.'s land is worked on the share plan, that is, they pay rent, provide manure, the ploughs and the seed, and the cultivators find the manual labor and cattle labour, and get from one-twelfth to one-sixth of the cotton yielded for harvesting it, while half of the remainder goes to Messrs. Sabapathy Moodelliar and Co. as their share: they are satisfied with the arrangement, and would be glad to get a larger area of land on the terms on which they hold much of that they now have. It appears to me much better that land should be thus utilized, instead of lying waste; there would be no difficulty in drawing up an "improving lease" to secure the interests of the State. All new enterprises are uncertain at first, and if capital must be attracted to agriculture, some inducements must be held out, and Messrs. Sabapathy Moodelliar and Co.'s plan of providing capital has much to recommend it. This district appears to demand exceptional treatment if it is correct, as is asserted, that in the past 10 years, the population has diminished one-third, while there is one-third less land under cultivation. Mr. Sabapathy Moodelliar does not confine his attention to deep culture; he is quite aware that, though deep culture is one of the most effective means at the command of the farmer for improving the output of his farm, it is only one of the means that are available for securing this desirable object. He is giving attention to the one manure, so abundant and yet so little used in India, viz., poudrette, has made arrangements with the Town authorities of Bellary, Adoni, and Cuddapah for obtaining supplies. Last year he manured a considerable area of black cotton soil with this manure, at the rate of about one ton per acre. The results were very satisfactory, but he considers that the rail charge is too high for such bulky manure. The rate appears to be 5 annas per waggon per mile, and the consignee loads and unloads the manure. The rate does not appear to be excessive, for it is only about half-an-anna per ton per mile. Certainly the so-called poudrette usually made is so poor, it will not bear the cost of distant carriage; it should be used only near the places where it is collected and prepared, or be made into a more concentrated manure. Messrs. Sabapathy Moodelliar and Co. consider that the land manured with poudrette last year shows this year also a marked superiority over the unmanured land; and the portions I saw certainly bore out this conclusion. Messrs. Sabapathy Moodelliar and Co. are, I understand, making arrangements for collecting and

crushing bones for use as manure. It is not only in cultivation and manuring that Mr. Sabapathy Moodelliar is taking such a leading part, but in the introduction of cotton seed of superior kinds; he understands that a deeply-tilled and well-manured soil can be much better employed than in growing inferior, indigenous cotton. He has therefore imported into the district large quantities of the following varieties:—Coimbatore, Hingunghat, Broach, Dharwar, Tinnevely and Dhollera, with which most of the land he holds is cropped. Mr. Sabapathy Moodelliar is a firm believer in thin seeding, and has his cotton seed sown at the rate of only about 7 lbs. per acre, in lines wide apart. He discourages as much as possible the culture of crops between the lines of cotton, in order that the cotton plants may benefit fully from the soil. My own opinion is that his anxiety on this score is unnecessary, if care is taken in selecting a suitable crop for growing between the lines of cotton, for during its early growth cotton does not need much from the soil, and a cereal crop may be grown and removed before the cotton needs the whole of the land; of course, when both cotton and a cereal crop are grown on the same land, more is demanded of the soil, and it must therefore be manured more highly than if cotton only is to be grown. The crops I saw on Messrs. Sabapathy Moodelliar and Co's land were almost invariably much better than those of the adjoining land. In passing through the country, it is quite easy to discern by the crops the fields that have been deeply ploughed. Last year the cotton crop was very bad in Bellary, owing to the failure of the rains, and the average outturn on Messrs. Sabapathy Moodelliar and Co's land was only about 37 lbs. of clean cotton per acre; but adjoining lands treated in the usual way did not give 10 lbs. per acre. One or two fields of low situated land gave over 100 lbs. of clean cotton per acre. Judging from the appearance of the crops when I saw them, the outturn this year will be very much larger than that got last year. The absence of a variety in cropping is a great evil in the Bellary district, and Mr. Sabapathy Moodelliar appears to recognise this fact; he is doing what he can to introduce other crops on the black soil, such as wheat, sugar-cane, ludigo, and fibre crops. Mr. Sabapathy Moodelliar has shown a practical interest in agricultural education in having given employment to two or three graduates of the School of Agriculture in connection with the enterprise under notice, and he is a warm advocate for a status being accorded to agricultural education equal to that of medical and engineering education. Before concluding this report, I wish to bring to notice one or two points which specially attracted my attention while in Bellary: first, the necessity for screens, in the shape of plantations or fences, for sheltering stock and crops in severe weather; at certain seasons of the year, when the cold wind prevails, which sweep over these treeless plains, farm stock suffer severely. Efforts should, I think, be made to induce those interested in the land, who possess the means, to do what they can to raise screen fences or plantations. Some portions of the district where mixed soils prevail are not unlike the country around Erode, in the Coimbatore district, where a hedge shrub is grown largely known as "Moolukiluwai," which is an excellent shrub for forming fences either for shelter or for enclosing crops. I have arranged with the Sub-Collector of Erode for a supply of cuttings of this thorn plant to be sent to Bellary at the proper season, but there are probably other shrubs equally well suited. Another point of interest is the water-supply for man and beast. I heard of instances in which, even in a good season, villagers have to send as far as five miles for their daily supply of water,—due, in some instances, not so much to the absence of water, but to the water of their wells having become so saline as to be unfitted for drinking. Wells, which at one time contained good water, are now for this reason abandoned. It would, I think, be a great boon to the people in many places, if, in the dry season, a small portable engine, with a centrifugal or other pump, could be sent by Government to the accessible places for employment in emptying some of these wells, which cannot in many instances be emptied by the means at the disposal of the people. I believe that in most instances the increase in the quantity of salt in the water of these wells is to be attributed simply to the concentration of the salt brought in the natural spring water due to the loss of water by evaporation over a term of years, and that, if the comparatively speaking concentrated solution of salt in the wells be removed, and the wells be thoroughly cleaned out, the fresh supplies of water when the springs have come thoroughly into play will generally be fitted for drinking. The experiment is, I think, one well worthy of trial, for, if successful, much good would result. But more than this is necessary; new wells are greatly required, both for enabling the people to get water for themselves and their stock, and for raising crops and trees where the soils are suitable. I venture, therefore, to invite attention to the suggestion I made in my report on the Coimbatore district relative to the employment of a few squads of men in boring for water in different parts of the district where water is especially required and is likely to be met with. There are other points of interest connected with the improvement of the district, but they need more careful local investigation than my short visit permitted.

The Director of Agriculture remarks on this report:—"Referring to the *metayer* system adopted by Mr. Sabapathy in his agricultural operations, Mr. Robertson appears to advocate the adoption by Government of a similar method, so as to bring into cultivation a large area of land that is now lying waste. But not to speak of the fact that the *metayer* or sharing system, however successfully it may be worked by a private owner, has been discredited everywhere by Indian history as a Government method of agriculture, and revenue, there remains the fact that the lands now waste are so chiefly from the want of people to cultivate them. Rather less than a quarter (not a third, as Mr. Robertson puts it) of the population of Bellary disappeared with the famine, and something less than a quarter of the land in occupation before the famine is now lying waste and unoccupied. The people of

India are not migratory, and it is improbable that these waste lands will be occupied by immigrant settlers. Mr. Sabapathy's experiments with *poudrette* are said to have been very satisfactory, but the report of them would have been more interesting and useful if accompanied by comparative statements of results. Mr. Robertson's suggested remedy for the cost of carriage of this manure to places distant from where it is made, viz., to make a more concentrated *poudrette* and to use it only near the places where it is collected and prepared is unintelligible, for the only purpose of concentration must be to fit it for carriage, while concentration is unnecessary if it is to be used only where it is collected and prepared. With reference to the planting of 'killway' hedges to screen crops and stock from blast, I have to observe that in Coimbatore it is necessary to supplement for some crops, such as the betel vine, the killway hedge by high screens of matting. I am afraid that the remedy for brackish wells proposed by Mr. Robertson in the same paragraph 14 would have only a very temporary effect. The soil is impregnated with salts of various kinds, and these salts as they get dissolved infiltrate into the water. As the water gets low, the water of course gets more heavily charged. The only lasting remedy is to condense it—a thing easily done by people who know so well how to distil—or to get water from a lower stratum, but this would be generally possible only by means of artesian wells, and they are not always possible."

The Board of Revenue in submitting this report to Government consider that Mr. Sabapathy Moodelliar's efforts to improve the agriculture of the district where he resides are most praiseworthy, and he deserves every encouragement. It occurs to the Board that in two directions the Government might possibly afford valuable assistance to the people in such a district as Bellary. One is by showing them how to extract from the existing salts, which are so abundant in the soils, those nitrogenous elements which are the great desiderata in manures. Whether this can be done in a cheap and a practicable manner (if it can be done at all), and how it is to be done, are questions for a competent analytical or agricultural chemist, such as Dr. Nicholson or Mr. Harman of Bangalore, to decide. The Board believe they are correct in stating that at all salt factories a large amount of potential manures is lost in the mother liquors, which are thrown away from ignorance of their value, and, reasoning from analogy, it would appear that similar properties are to be discovered in the salts of the soil, which in their natural condition are usually noxious to vegetable growth, and by filtration into wells render the water undrinkable. The possibility of getting rid of the saline impregnation is therefore a matter of the deepest interest and importance, and the Board would urge on Government the desirability of having the subject scientifically investigated, considering it to be one on which funds might very advantageously be expended. The other point is the sinking of artesian wells, which have indeed lately received the attention of Government in the adjoining district of Anantapur (*vide* Board's Proceedings, dated 6th December 1882, No. 3024). More favourable conditions than those reported on for Anantapur would probably be found in the neighbourhood of Bellary; but it would be well to have actual experiments made by a specially-qualified person, acting in consultation with a geologist.

Order of Government, dated 16th June 1883.

The Government concur with the Board in considering Mr. Sabapathy Moodelliar's enterprise very laudable. The difficulty and cost of effecting repairs appear to be the chief obstacle to the more extended use of European ploughs. Mr. Sabapathy will be supplied with a copy of Mr. Benson's late report on Agricultural Implements suited for introduction into India, together with the order thereon. The Government do not entirely apprehend what is the proposal made in paragraph 3 of the Board's Proceedings, but any practical suggestion will receive their attention. It has been ascertained in the North-Western Provinces that barren saline lands can be reclaimed and their saline impregnations removed by planting *atriplex nummularis* (Salt Bush), and the Superintendent, Government Farms, has been directed to procure a supply of seed for trial at Saidapet. Possibly Mr. Sabapathy Moodelliar may wish to make an experiment at Bellary, in which case Mr. Robertson will supply him with some of the seed. The subject of artesian wells, the cost of which the Sanitary Commissioner believes has been greatly over-rated, has lately received considerable attention, and efforts are being made to discover suitable localities for borings.

SELECTIONS.

BEE CULTURE IN INDIA.

NOT having met with beehives in the plains during a long residence in India, it occurred to me that bee-keeping, as carried on in Europe and America, might be introduced into India with great advantage to the rural population. When in England I wrote to the India Office for any available information on the subject of Indian bees and apiculture. This led to the Secretary of State addressing the Government of India, and the Government of India sent out a circular to local Governments and Administrations asking for information on the subject. The local Governments having collected information and furnished reports, these reports have just been issued, with a Resolution of the Government of India on the subject.

The reports contain much information of interest and importance, but necessarily, from the nature of the subject, the writers in most cases not having the necessary knowledge as bee-keepers or naturalists, erroneous opinions are

expressed, and some facts of primary importance are so incompletely stated as to be of little value. Other reporters have given opinions which, however they might apply to limited areas, are inapplicable to the whole of the plains of India.

It appears the honey-bee is found all over India—some reporters mention six or seven kinds as indigenous to their locality; in all cases the bees are mentioned by native names, and as these differ, and the descriptions do not include the generic characteristics, the species cannot in most cases be identified, and in some of the cases, where scientific names are given, they are evidently wrong. It appears probable that varieties of the unicombed bees *A. dorsata* and *A. florea*, and the multicombed bee, *A. indica*, are common over the greater part of India, Burmah, and along the Himalayan slopes; that some variety of *A. indica* is the kind generally cultivated. This bee is similar in habits to, but not identical with, the European bee, as some have supposed. The bee being so generally diffused is evidence that it might be cultivated with profit over the greater part of India. Very generally it is kept by the natives in the villages in various parts of the Himalayas and of the Panjab hills and Cashmere in the walls of houses; in the Beas Valley hollow logs are used as hives, and moved from place to place to get the bees pasture; in the Khasia and Jaintia Hills hollow logs are used as hives, and these are thatched with grass. In Pegu logs are used, the ends of being covered with skin. The Nepalese, Bhutias, and Lepchas about Darjeeling use hollow log hives. Although it is reported that the natives of lower Bengal do not keep bees, I find they do keep them in earthen vessels inserted to the walls of the houses, and I purchase stocks of bees as I require them from this source. In many cases the bees are enticed into vessels or hives by putting these in suitable places during the swarming season. In other cases, as in Cashmere, the hives are stocked by capturing swarms in baskets, as in Europe. The Khasias capture the queen and tie her with a thread or hair to a stick on which the bees swarm, when they are carried away and hived by the owner or sold. The queen is tied in the hive to prevent the swarm absconding. On the Panjab hills the bees are fed, as in Europe, on sugar and flour during cold weather. Even the best native attempts are very rough and cannot be very productive. The honey is taken in most cases by using smoke to intimidate the bees; in some cases, with the smaller bees, they are driven out by the blowing into the cavity. A powdered plant is blown into the nest in Gaujam. The honey of the larger wild bees is usually taken at night, torches being held under the bees. In some places there is a belief the honey must be taken during full moon, or the bees make away with it; in other cases the idea is they make away with it if it is not taken on a dark night, as disturbed bees always fill themselves with honey if possible. It is obvious how these notions arise. In some cases the small kinds are merely brushed off the combs; in others the comb is put into a bag and all the bees destroyed. In many cases the face of the man taking honey is covered, and Assam gluger is chewed to keep off bees. The honey is harvested at certain times of the year, but it is noteworthy that there is usually more than one honey harvest during the year. In Harasol and Touk the honey is taken at the end of April and beginning of May; Coorg, May and June, but stated to be harvested several times a year; North-Western Provinces, twice, May and October; Sibsagar, twice a year, February and October; Khasia Hills, three times, twice in spring, once in autumn; Cashmere, twice, June and November, or December; Darjeeling, March, April and October. Near Calcutta I find honey is taken just before the rains in June. It is very difficult to arrive at the quantity of honey yielded by one stock of bees, and in comparing figures the identity of the bee is doubtful. In Burmah three pints of honey and 30 to 35 tolahe of wax are taken from a bee building in hollow trees. In the Central Provinces 20 to 25 seers of honey and 5 to 8 seers of wax are taken from a bee found in white-ants' nests. Four to five seers is taken in May, and two to three in October, in the North-West. In Coorg 5 to 20 seers. In the Wynad *A. indica* is said to yield 6lbs. three or four times a year. In Trichinopoly district a bee building in hollow trees yields 4½ to 18lbs., and in Gaujam the yield is 12 Gaujam seers. In Indore the yield is 16 to 24 seers for the large bees, and 8 to 12 lbs. for the smaller.

A Burmah bee half-an-inch long yields 24lbs. honey, 5lbs. wax; another 1 to 2 lbs. wax and two quarts honey. In the Khasia Hills six seers of honey are taken. But these figures are very rough approximations; in some cases the proportion between wax and honey is apparently incorrect, and in no case is there data to draw any conclusion upon as to what these bees would yield if properly treated. The best European varieties when wild in America yield scarcely anything as compared with what they yield when properly treated. In some places the larvae of the bees are eaten; they are said to taste like cream. The Deputy Conservator of Forests, Salween Division, vouches for their being a most delicate dish when roasted and served on toast. If a taste for the roasted maggots should spring up, India would have the honour of supplying a new article of diet, and a profit would attach to an improvement in apiculture not thought of hitherto by the best authorities.

It is probable the bees swarm at more than one season of the year. More information is required on this most important point. In Sibsagar they swarm twice, viz., in March and October; in the North-West they swarm in April; in lower Bengal I find they swarm in May or earlier, and I captured a fine swarm of *A. indica* the first week in June. The treatment of the honeycomb harvested is abominable, the product is necessarily very inferior, and keeps badly unless specially treated; the pollen must in many cases give the honey an unpleasant flavour, and the fact that it was expressed with dirty hands or through a foul blanket, and that a vast number of larvae were crushed with the comb, must make the honey unacceptable to Europeans at least; while the

knowledge that it is very generally adulterated must seriously impair the demand amongst natives. The methods employed are squeezing the comb in canvas bags or in a blanket twisted by two persons; squeezing by the hands, or in very few cases by means of a kind of large lemon-squeezer, considerably introduced by some gentleman in the Forest Department to prevent the filthy practice of hand-squeezing. As the honey is often not ripe, and is commonly foul, it does not keep; it is boiled thicker, or till scum ceases to rise, or it is kept in new earthen vessels with a very little wax. The rationale of the earthen vessel is probably the evaporation of the watery constituent and consequent ripening, as it is called in Europe. Boiling injures honey. In Gaujam the comb is not cleared, but broken up and sold no doubt—a dirty mass of wax and honey together. Wax is purified by boiling the comb and letting the water cool, or by squeezing the hot mass after boiling in a coarse cloth. The price the honey and wax fetch differs widely. In Coorg the honey fetches only 2 to 3 annas a pound; the wax sells for 5 annas 9 pils to 8 annas 8 pils, and is exported to Madras; at Kotagiri (Nilgiri Hills) honey is 12 annas to one rupee a bottle. In British Burmah honey varies from 2 annas to 10 annas a lb, and wax 12 to 14 annas. Mr. Hunter of Landour tells me he gets 12 annas a pound, and demand is far greater than the supply. A description of honey, believed to be made from lotus flowers only, is used by native physicians in eye affections, and fetches a very high price. In many cases honey and wax are exported from the places where procured, as in the cases mentioned above, e.g., from Mergui, was valued at Rs. 750 and honey valued at Rs. 8,000, the product of wild bees, is exported yearly to Moulemein and Rangoon; about 100 maunds exported from Ulwar into the British district of Gurgaon, &c. The revenue on the collection of wild honey is very trifling. In Coorg it is about Rs. 270 a year, but several Forest Officers think the revenue from this source might be increased. In Cashmere all honey on Government tracts is the property of the Maharaja. Rent is paid to the house-owners who maintain the hives; when lands are leased a cash value is fixed and added to the Government share of the revenue due; when the Government share is collected by division of harvest, two-thirds of the honey is appropriated by the State, and one-third by the zemindar. It is stated that honey in Coorg is sometimes unpalatable or injurious when a particular weed is in flower; it is also said to be occasionally acrid and injurious or poisonous in the Wynad. It is possible there is some exaggeration in these accounts. In Germany, although bees are kept most extensively in many parts, no case of the kind has ever been recorded, so that a German poet has written, bees take the sweets and leave the bitters behind; in France, at certain seasons, in some localities the honey is somewhat bitter, but this honey is given to the bees, and the honey for sale is taken before this season.

The stings and tempers of some Indian bees are reported as very bad indeed, but my limited observations have not confirmed these statements, and such statements to be of value must be made by persons experienced in handling bees, and who know what to expect when stung. The European bees leave behind their stings and poison bladder; the pain may go away in five minutes, or may last very much longer; the swelling may be trifling or considerable, and last two or three days; the severity depends on the part stung, and how often the person has been stung before, as after a number of stings the pain and swelling become trifling, and on the state of the bee at the time, as some stings are far worse than others. The temper depends on the weather, state of honey harvest, &c. I find *A. indica* fairly good tempered and easily handled, but its sting on my person is somewhat more severe than the sting of the Italian bee; this may arise from the fact that I am more inoculated with the Italian bee's poison. *A. indica* is much smaller than *A. ligustica*. Mr. Ritta, who kept Indian bees at Shillong, and Mr. Hunter of Landour, who keeps the hill bees, agree in not finding fault with the temper of the bees. In India, as in Europe, there are absurd superstitions connected with bees. The Burmese think a swarm settling near a house unlucky; in England it is considered lucky. Possibly there are other superstitions as gross as the English one, that if the owner of the bees dies, and bees are not informed by tapping on the hive, the bees will die. I was gravely told of a case of this kind in Essex. I found the unfortunate bees had been starved to death, but I could not convince my informant.

As usual, there are several remedies for stings. One remedy is bruised tamarind leaves boiled in water; this is said to reduce the swelling. The Khasias apply *pan* leaf, which is said to allay the pain. These applications, particularly the latter, are too generally applied to such purposes for their specific virtues to command credence. I doubt if these remedies are likely to supersede the American one in general use, which is—"forget the sting as quickly as possible."

It does not appear that there is any prejudice against using the products of the honey-bee; honey is eaten by the natives; in some parts large quantities are consumed at wedding festivals; it is eaten with rice, with bread, and with fruit; it is used to preserve ginger and fruit; it is very widely used as medicine; for offerings to and for anointing idols. Wax is used for making wax-cloth, in ointments, by shoemakers, &c. It is commonly adulterated, so that it is difficult even in Calcutta to get wax sufficiently pure for making artificial combs for bees. It appears many attempts have been made by Europeans to cultivate indigenous bees, but these attempts have not been very successful, judging from the meagre accounts given of them; in no case have the appliances which make bee-keeping certainly profitable been applied and the hives used are either out of date or never were in general use anywhere. Several reporters seem to think the frame hive used all over Europe and America very difficult to make, and requiring great exactitude; whereas any native village carpenter could make

a hive as good for practical purposes as any sold by the hive-makers in England. A ten- or two-bee-cases would supply the need. The books referred to are far from the latest and best. Mr. Cowan's little book (1s. 6d.) and *Modern Bee-keeping* (4s.), which are the best practical works in English, are never mentioned, to say nothing of the learned works published in Germany and America, the Bee Journals, and the Bibliography of Agriculture published in Italy. The following experiments were made by Europeans:—Mr. Freund had, when writing, one hive; he had kept bees for many years on the Nilgiris, but gives no particulars of yield, hive, variety of bee, or mode of manipulating. Mr. Freeman kept a stock of bees which swarmed on his premises. The Superintendent, Government Gardens, Ootacamund, a few years ago, kept a stock for three months in a deal-wood box; he fed them with syrup, but they ungratefully absconded, leaving a few empty combs. They probably became queenless, and could not raise another queen. Miss Cockburn, of Kotagiri, Nilgiri Hills, has hived bees in wooden boxes for years; her system is simply to remove all the combs but one as soon as stored, leaving one to prevent the bees absconding. This method has the one merit of simplicity, but it is no better than the native methods, and cannot be very profitable, excepting on the old principle that robbery is all profit. Mr. Harvey, N.-W. Provinces, kept as many as 80 hives in the Chumba hills; he preferred the grotto hive, a hive made up of separate frames: this hive is very little used, and is unsuited to India, as it is a bad protection against heat, cold, and insect enemies; is expensive to make well, cannot be opened and closed without crushing the bees, and is troublesome to manipulate. Mr. Harvey did not use the extractor or comb foundation, so the honey yield must have been small; but he considers the sale of this honey would give him a clear profit of 100 per cent; possibly Mr. Harvey would have made ten times this profit with fewer very strong stocks and proper appliances. An attempt to keep a hive of Chumba bees in Mooltan failed; probably they required stimulating food to keep up their numbers; not getting this, they appear to have dwindled, and become a prey to wax-moth and other enemies of weak stocks. Mr. W. Morgan, Deputy Conservator of Forests, Madras, has experimented by using beer-casks as hives, and he proposes a hive made of clay with an appliance for supering. Mr. Morgan's proposed hive would be no better than the old English skep; with it the modern practice of bee-keeping could not be carried out, and the produce would be often nothing, as bees will not work in such supers without some inducements, and there is no arrangement for taking honey from the body of the hive. The Rev. T. Mayer, Bannu, seems to have taken the matter up, and the Punjab Government proposes obtaining model hives and appliances from England. The book used appears to be Hunter's. I would recommend Cowan's book and the German hive of Dr. Dersson. The English firms make expensive appliances, many of which are quite unnecessary, and most are too expensive for profitable employment.

The Government of India reviewing the Reports, concludes that several varieties of honey-bees are found in every province of India where there is sufficient forest or jungle, and that the honey of some of the varieties is good and in considerable demand; (2) that efforts have been successfully made in the hills by Europeans to domesticate Indian bees, but that the bee culture is only practised by natives in the rudest way; (3) that it is very doubtful whether the bee could be domesticated in the plains, owing to the dearth of flowers during the three or four months preceding the rains; (4) that in Southern India persons (Mr. Stormont of Bombay and others) have given up all attempts to domesticate the most common variety of bee found there on account of its intractable nature. The Government further concludes the industry is unlikely ever to be one of great importance in India. It can only be followed in the hills where flowers abound throughout the greater part of the year, or in forests where food is equally plentiful. The Government does not see its way to taking any practical steps in the direction of improving the system of bee-culture in the hills and forests; but opportunity is to be taken of the Calcutta International Exhibition to make further inquiries in the matter. The Local Governments are invited to send specimens of honey, naming, if possible, the varieties of bee which produced them respectively. It is much to be regretted the Government resolution should discourage attempts at improved bee-culture in the plains, seeing that no real trial has been made by an experienced bee-keeper. Botanists, including Mr. King, tell me there are flowers in Lower Bengal, for example, for ten months; that only in December and January do they fail. The rains have apparently now commenced, and as to there being a dearth of flowers before the rains—that is, the swarming time, and I found my bees bringing in pollen from, I think, January to the present date—I consider the conclusion erroneous as applied to Lower Bengal. Certainly, if flowers existed all the year round, the honey-bee would not need to store food and would be economically valuable; that for four months there are no flowers is an admission which proves, not that the honey-bee cannot be profitably cultivated, but that it can be far more profitably cultivated than in Europe and America, countries having severe winters, during which there are not only no flowers, but the temperature is so low that the bees cannot breed to keep up their numbers, so that it takes two months of spring weather and judicious feeding to strengthen the bees up to profitable numbers. Herr Vogel, one of the greatest German authorities on the subject, says, "most localities in Germany are honey-poor (*honigarm*), but there is in the wide German Fatherland, indeed, no place in which bees could not be kept with some success." Honey-poor localities are defined as places where all notable honey harvest ceases with mustard flowers, and if from harvest through autumn the bees get enough for themselves and their brood the bee-keeper must be considered fortunate. A neighbourhood is generally said to be honey-poor when there is no honey harvest during autumn, and such neighbourhoods form the greater part of

ENTOMOLOGIST.

topography, empty hive, etc. Bees have to be fed up very generally kept by small farmers, who pay 10 marks only for each requiring six weeks or two months in the hives, &c. In England the stocks, during which there is no dearth of flowers, are fed up for the winter more there is no severe winter in the plains. As in India, generally, dearth of flowers, the bees can be fed on the two months sugar, and so the breeding being maintained, the stock will last ten months instead of only from May to October, as in England, and swarms could be made artificially at almost any time. If without any protection—artificial comb, feeding, stimulating, breeding, and other devices of the agriculturist—the bees collect stores sufficient to offer a prize worth taking, surely it is a scarcely justifiable conclusion that the plains where this occurs are unsuited to bee-culture. As to the attempts made to cultivate bees, I do not think any but most favourable conclusions can be drawn from the cases reported. The Rev. T. Mayer, Bannu, has taken the matter up, and he appears to be acquainted with the subject, but no results are given. As to the native methods, even that of Kashmir, which appears humane, as the bees are not destroyed, is probably inferior to the old English one of killing the heavy and light stocks with sulphur; for the old brood comb must harbour wax-moth and other enemies of the hive bee. As to enemies, the greatest is, I think, the wax-moth, which is very common in nests of the indigenous hive bee in the plains. I have taken nests almost destroyed by it; but this could be met by giving no more comb than the bees can cover, and contracting the hive. If these measures should not absolutely keep down the moth, then the Italian bee, if introduced and properly managed, would do so, as it has in America. As to the temper of the Indian bees, as a German bee master said to me, "bees are bees," and much nonsense is talked on this subject; there is no evidence of any value that the Indian species of hive bee is worse than other species, and I have evidence to the contrary as well as considerable experience, for I have performed most difficult manipulations in transferring combs to frame hives. I have three stocks of native bees now in Calcutta, and they are very mild-tempered. I handle them without smoke, veil, or gloves. Mr. Stormont, referred to in the Government resolution as having found native bees vicious, does not give information as to his mode of manipulation; and as I understand his report, he simply refers to uncomb bees, and not to the kind likely to take to a hive, viz., the multicombed bee, living in holes, in trees, in rock cavities, &c.

It is quite possible the multicombed bee of the plains may not be so profitable as the bee of the hills; its swarms may be lighter; it may be exceedingly prone to swarm and breed drones, &c. This remains to be proved; if hill bees are much better, then queens of hill bees or small stocks may readily be imported into the plains, and no difficulty will be found in keeping them over a very large area, independent of forest and jungle. Should these be less profitable, as I think very probable, than the European varieties, then the Italian bee could be cultivated, I believe, with success, and where mustard, legumens, fruit trees, &c., are cultivated, I believe bees would be found highly profitable.

As to attempts to introduce the European bee, these have failed from well understood causes; the late Lady Anna Gore Langton imported some bees when her brother, the Duke of Buckingham, was Governor of Madras. The experiment failed. Mr. Woodside, a Missionary, N.-W. P., imported a stock of Italian bees at his own expense, but the bees perished. An Italian exporter tells me he sent bees to India via Bombay; of the fate of these I have not heard. I imported three stocks and two spare queens, with the result that I have two fine stocks which have done very well during the hot weather in Calcutta, and they find both honey and pollen. I have not swarmed them, because the queens are so young that I cannot get any drones; I have not taken honey in any quantity, because I have fed up the bees to make them breed, as I naturally require bees, not honey—the bees being far more valuable than honey. The heat has not affected the bees injuriously; they have done remarkably well, and are a living evidence that the Italian bee can be cultivated in the plains. I find the native bee very prone to swarm, and the stocks are light; it remains to be seen if the native bee can be made as profitable as the Italian; but if not, the Italian may be cultivated. As to the uncomb bees, I do not think *Apis Florae* of economic value; *A. dorsata* remains to be tried, as nothing is known concerning the mode of cultivating it; a long thatched open-sided hive would probably have to take the place of the usual closed hive.

As to hives and appliances to commence with, one stock in an English frame hive should be tried for profitable cultivation; probably a modification of the German hive, built of clay or straw, would be found most suitable. As to appliances, I think natives should rely rather on the centrifugal extractor, by which honey can be taken from any part of the hive without damaging the comb, than on supering, at any rate at first. I made an extractor for Mr. Hunter for about Re. 1-8; the cheapest English one is 15s. I recommend Mr. Cowan's book, costing 1s. 6d., for beginners, and I strongly dissuade anyone not thoroughly acquainted with the subject from importing foreign bees; it is not a very difficult matter to order a stock of bees from Europe, but when the few surviving bees reach their destination (if any survive), months of care, guided by knowledge and experience, are required to prevent their total extinction, and success is very doubtful. I would strongly recommend planters and others having land to keep bees, and anyone who has a verandah in which to place a hive, or a tree under which it could be placed, may derive much pleasure and a proportionately large profit from a hive or two, commencing with two at most. I have a few books which I lend to persons desirous of trying to keep bees, and I should have much pleasure in giving any assistance in my power to would-be bee-keepers. Mr. Hunter tells me he has eight hives in his verandah; he gets excellent

THE INDIAN

honey, and the thousands of bees going in and out of anyone but the keeper (bees object to foul air—shortly to persons sit in the verandah near the hives, and Hunter will give will, I believe, in this matter read distribute the stocks of Italy them a factorial in the hills.

KUDIMARAMAT; OR, UNPAID VILLAGE LABOUR.

It is satisfactory to find that legislation is at last to be attempted on this important subject. The question has been so long before for decision that a doubt arises whether the usual evils of prolonged waiting have not supervened. So long ago as 1869, the Public Works Commission recorded among the results of their enquiries—(1) "That customary labour has not been afforded to the extent necessary or formerly prevailing; (2) that the difficulty of enforcing customary labour has increased; and (3) that customary labour should be enforced by enactment." Fourteen years have passed, and yet we believe that no Bill on this subject has been introduced into the Legislative Council till now. The Hon. Colonel Sankey has taken heart of grace, and introduced the Bill that was published in the *Fort St. George Gazette* of the 1st May. The subject is no doubt beset with difficulties. Not the least is the plethora of doctors who have been ready and anxious to prescribe for the patient. The minor irrigation works of the country are the patient, and the unfortunate sufferer has been dying of neglect and inanition for the last twenty years, while doctors learned in administration have been discussing, if not quarrelling, over the remedies.

The Bill introduced by Colonel Sankey, in short, contains only fifteen sections. We propose to criticize its provisions in some detail. Section 1 extends the Act to the whole Presidency of Fort St. George, excepting the districts of Madras, Malabar, South Canara, and the Nilgiris, and the canals and distributaries irrigating more than one village in the Godavery and Kistna deltas. The wisdom of excluding canals that irrigate one village only is questionable. A canal affected by the law would cease to be affected by it, if now or hereafter it irrigated half-an-acre in the area of another village. It would be better to omit all reference to the deltas, for, by Section 2, the Government may exempt any district or part of a district, and any locality or work from the provisions of the Act. This power is ample for all purposes of exclusion. Section 2 lays down what work is to be performed by Kudimaramat, or unpaid labour. There is much confusion of language in the wording of many sections of the Bill, and careful revision by a lawyer or a legal draughtsman is very necessary. The word "landholder," which is used and defined in the Local Funds' Act, 1871, and which would be applicable throughout the present Bill, is nowhere made use of. In Section 2, landholders are referred to as "those who own (lands) in whole or in part." In Section 5 we have "the owner or proprietor of the land." The latter, interpreted with legal accuracy, would bear a more restricted meaning than the former, and yet both are apparently intended to bear a meaning exactly the same. Similarly in Section 3, works are described which are to be done "by those . . . who cultivate land." In Section 5 it is laid down that under certain circumstances "the actual cultivator or tenant of the land" shall be bound to contribute the quota of labour. It is clear that a tenant need not necessarily "cultivate the land;" he may leave the land fallow, or he may employ cultivators under him. In this case, therefore, Section 5 extends the meaning of Section 2 as regards cultivators or tenants, just as it restricts the meaning as regards the landholder. In both sections the meaning should remain the same. The adoption of the terms "landholder" and "tenant" as used and defined in the Local Funds' Act would remove the difficulty. Section 2 defines the repairs to irrigation works to be done by unpaid labour. "(1) The filling up of gullies, ruts, and holes, especially at the back of revetments, &c., &c." The words we have italicized should be expunged. If the law requires the filling up of holes, &c., there is an end of the matter, and it matters not whether the holes are at the back of a revetment or in any other part of an irrigation work. To devote special care to a revetment may properly form part of an executive order, but not of a legal provision. To take a parallel case, the law provides punishment for theft generally, and all special cases are included, and it would be superfluous to say "whoever commits theft, especially of pocket handkerchiefs, shall be punished with imprisonment, &c."

Clause 2 runs as follows: "The prevention of the growth on village irrigation works of prickly-pear, wild croton, young trees, and other vegetation endangering the safety or concealing the condition of the work." This is a clause capable of affording infinite legal wrangling in the Collectors' Courts. Prevention may be better than cure, but if prevention fails, is there to be no attempt to cure? Unpaid labour is to be applied to the prevention of the growth of certain vegetation, but not to the removal of the vegetation. If a young prickly-pear does appear above ground, or a shoot of wild croton, or a seedling, the law fails. Labour is to be applied to prevention, not removal: *a fortiori*, unpaid labour is not to be applied to noxious vegetation already in existence at the time the Act comes into operation. But the concluding part of the clause must in any case render the first part inoperative. No vegetation can "endanger the safety or conceal the condition of a work" until it has actually grown up to some extent, greater or less. But it is only vegetation of this special kind the growth of which is to be "prevented." The most acute legal intellect, we venture to say, would find it hopeless to clear a track through the word-tangle of this section.

AGRICULTURE follows: "The preservation of such bushes and grasses have been planted for the protection of the interior water-courses of bunds of tanks." This presumably means the appointment of watchmen, as it is mainly by keeping off cattle that bushes and grasses are preserved. But if more, as the law is now drafted, can be done. If the bushes and grasses are destroyed, unpaid labour is not to be employed for replanting them. But what unknown power is to step in and do this most essential work? Again, why are the interior slopes of bunds of tanks to be alone preserved? It is occasionally of much importance to plant up with grass the external slope of a bund. Why should the preservation of the grass on the internal slope of the bund be left to the villagers, and that of the external slope to, say, the Engineer or the Collector?

Clause 4—"The clearance of silt from sluices, supply and distributing channels of tanks, spring channels." With respect to this clause we would enquire how it is to be determined whether or not a river-channel is maintained by the State. Does it depend upon whether an allotment of State funds is made in any particular season or not? Allotments for clearing river-channels are frequently made at intervals of several years. Are such channels to be regarded as "maintained by the State," *in perpetuum*, or as sometimes maintained by the State and sometimes not? Again, can the Collector or the Engineer, either or both of them, announce that a channel is no longer to be maintained by the State, and in such case, will its care thenceforth devolve on the village community?

Clause 5—"The clearance of spaces between the upright stones of calingulals (waste-weirs with upright stones) and the regulation of calingulals, according to the requirements of the season." The introduction of a definition of the word calingulah into the body of a clause of the Act is obviously objectionable. There is no need to use the foreign word "calingulah" at all. It means neither more nor less than the English word "waste-weir," which should alone be used. A calingulah is not, as here defined, "a waste-weir with upright stones." There are innumerable calingulals without upright stones. These, however, are dammed up with earth and turf to store up water in the tank, and need regulation and clearance like the rest. There is a further difficulty. Who is to define "the requirements of the season?" There is a vagueness about the phrase which does not commend it for use in a legislative enactment. For clause 5, we would substitute the following:—"5.—The clearance of waste-weirs, according to rules to be issued from time to time by the Collector." In the first two of the five clauses of section 3 "village irrigation works" and "irrigation works" to the village are specially referred to. But in Clauses 3, 4, 5, there is no such limitation. The use of the words in the first two sections and their omission in the last three is probably accidental. All irrigation works may be said to appertain to some village or other. There appears to be no need for the words at all.

Section 4 of the Bill lays down that in any district, or part of a district, the Government may by notification require that any work not included in Section 3 shall be performed by unpaid labour, upon being satisfied that such work has been heretofore performed by unpaid labour in such district or part of a district. This provision opens up an important question, the discussion of which must be reserved for another issue.—*Madras Mail*.

AGRICULTURE.

(From a Correspondent.)

PARIS, May 19.

M. GUFFART, to whom reverts the honor of the discovery of the preservation of green fodder in trenches, or *silos*, and known under the name of *ensilage*, reminds all whom it may concern, that he alone, and no one else, is the real discoverer of that process, which has revolutionized French agriculture, and is in a fair way of effecting the same in several other countries. It was in 1852 that M. Guffart first commenced experiments, which he continued during eighteen years with varying success. It was, however, only from the moment when he cut or chaffed the green maize, treading it closely in the trench, and covering the mass firmly with planking, stones, &c., to exclude the air, that success became established. Austria, as well as other nations, were simultaneously at work, but Guffart arrived first at the practical solution. He won the honor well, and it is only right to wish that he may live to wear it long. M. Le Bize, of Brant, continues his crusade in favor of the cultivation of parsnips as a forage plant, where climate and soil suit, and these conditions are pretty general. The root is largely entering into the ration of horses, resulting in an economy of oats. There can be no question as to the importance of parsnips for milch cows. It is to feeding cows on them that a large part of the reputation of the Channel Islands butter is due, and the same observation applies to the best butters of Bretagne, for in the latter country, where the brands are inferior, the cause must be attributed to objectionable methods of preparation. German agriculturists devote much attention to the food and the feeding of animals. In Saxony ground-nuts cake has been employed, and also rice flour, in the feeding of milch cows. In both cases the quality of the milk and the quantity of the butter have been improved, while the cattle, relishing both provender, had a decided preference for the rice flour. At Halle, cotton seed-cake has been added to the ordinary rations of milch cows and with beneficial results. Some of M. Pasteur's countrymen, and several Italian scientists, fall in question that gentlemen's important discoveries respecting the origin and causes of cattle plague. That disease is caused by animalism, floating about us, and only waiting the favorable conditions of humidity, heat, and cleanliness to propagate and . . . is a theory of which Pasteur does

not claim the paternity. Indeed, readers of Goethe's *Faust* will find the doctrine there published before Pasteur was born. But the latter claims, and fairly so, to have discovered certain infectious called microbes existing in the blood of stock, victims of pest, which, by their marvellous fecundity, deprive the blood of the animal of its oxygen, and so induce death. Further, Pasteur not only produced these microbes artificially, causing death when they were introduced into the system, but he prepared that very virus in so harmless a form, that when employed as a vaccine, the cattle inoculated with it remained proof against attacks of the malady, while stock, unvaccinated, succumbed. What has not yet been demonstrated is the efficacy of this inoculation for a longer period than six months certain. Experiments will in due course set this point at rest. The French Government has just given an additional proof of its appreciation of Pasteur's life-work by doubling his pension, by raising it to 25,000 francs a year.

There are many agriculturists in France more patriotic than practical. They belong to that class of short-sighted individuals who maintain that native breeds of stock can surpass the race of Durhams. Hence, the starting point of the angry discussions which rage. A few simple facts suffice to set the dispute at rest. In all the cattle shows held in France, they are the pure Durhams, or crosses, that invariably carry off the prizes. Every country in the world imports Durhams for breeding purposes, the Chinese being the latest. Where are such Durhams sought? In England of course; never in France. Again, the small farmers of this country have adopted the excellent habit of saving up till they have a sufficient sum, say 300 francs, to purchase a young Durham bull to serve their cows, and that animal is imported from the cradle of the short-horn.

The diminishing supply of good foreign tobacco has forced the French Government to consider the question of its home cultivation. For three years experiments in the south-western portions of the country have been carried on. The results have exceeded the most sanguine hopes. Last year, despite the cold wet season, the yield of tobacco was so satisfactory, that an important area of land is at present devoted to tobacco culture, soils of a sandy character being preferred, such being the kind on which the best brands of Havana are raised. Climate does not appear to be the decisive factor in tobacco culture. In the West Indies, tobacco is cultivated during the winter season, that which signifies a temperature equal to the summer heat at Bordeaux. The culture of tobacco can replace the destroyed vineyards, and another consolation has been found in the cultivation of China grass, or Ramié. The great obstacle up to the present against the latter has been the want of a machine to bark or skutch the stems, and set the fibre free, cleanly. Such is claimed at last to have been found, as a company has been organized not only to construct the machines, but to hire them out to the farmers. Further, the company in question guaranteed to supply seed and plants at reduced rates, and to take all the grass raised. In order to augment the supply of horses for the cavalry, the Minister of War has decided to place at the disposal of farmers, select breeding mares drafted from the State studs. The farmers will be allowed to employ the mares at light work, as payment for keep, but they must be covered only by stallions belonging to the Government studs, and those approved by the official Vet. The foals are to be registered at the nearest cavalry depot. If the mares after three years prove improper for reproduction, they will be taken back at the cost of the State.

M. Bonley, chief Veterinary Inspector, states that in the case of animals dead from a contagious disease, the best means to destroy the germs of the malady is to cook the remains, which can then be employed without danger for feeding pigs, dogs, &c. Care must be taken that while this diet suits during the rearing period of pigs, it is totally unfitted for fattening the animals. I think there are other reasons than the possibility of contracting the trichina disease for keeping American pork out of the French market. In England and Germany, where such vast quantities of that pork are consumed, the inhabitants do not suffer from trichinae. The truth is that American food importations are so cheapening the necessities of life, that farmers cannot obtain remunerative prices. Labor and other expenses, local as well as general taxation, the cost of machinery, &c., augment, and agriculture does not progress in proportion; hence, the secret of the situation. Everywhere vegetation is a fortnight late. This has told on stock-feeding, and has compelled animals to be prematurely sold, and at inferior prices. The future, however, is not gloomy. The vines and cereals promise well; forage will be less abundant. Farmers are not inclined to invest in implements. The sugar industry is declining owing to fiscal charges. On the contrary it is progressing in Germany and Austria. The French Budget of Agriculture allows a sum of 50,000 francs this year as prizes for the best cultivated small holdings. — *Madras Mail*.

FORESTRY.

NOTE ON FRENCH FORESTS BY MR. A. SMYTHIES, ASSISTANT CONSERVATOR OF FORESTS.

1. *Strasbourg*.—The forest of Strasbourg, or the Hohwald, is situated on the eastern slopes of the Vosges mountains, in what was formerly the Department of the Lower Rhine, and it nearly surrounds the small village and watering place called Hohwald. It belonged formerly to the Commune of Strasbourg, but, since the Franco-German war of 1870-71, it has been considered State property, and it is managed like other Crown forests in Germany.

2. The area of the forest is 2,135 acres; the total annual yield is 100 cubic feet, or about 100 cubic feet per acre; the total

annual revenue amounts approximately to 3,600*l.*, or about 1*l.* 12*s.* per acre, and the expenditure amounts to 300*l.* annually.

3. This is a most instructive forest to visit owing to the splendid natural reproduction of the two principal trees, and the regular young crops which have resulted from the regeneration cuttings themselves. Silver fir and beech constitute the greater proportion of the standing crops, and it is now many years since the regular method of compartments, as distinguished from the selection method, was first applied. There are some portions of the forest, however, where the young beech poles have been allowed to overtop the silver fir, and, though the latter has a wonderful faculty of shooting up and growing vigorously after many years of suppression, it is nevertheless obvious that, had the beech been cut away some years previously, the silver fir would be now much higher, more vigorous, and more uniform; in other words, the absence or neglect of clearings has here most certainly resulted in a loss of production and of revenue, for the fir is far more valuable than the beech. These remarks, however, are applicable only to a small extent of forest, and in the younger seed crops the beech is being cut away in time, and the fir will be able to shoot ahead from the beginning. The necessity of cutting back the beech in a mixture of silver fir and beech is explained on pages 81 and 82 of the "Elements of Sylviculture," by G. Bagnaris, London.

4. A comparison between the conditions of growth in the forest of Strasbourg and in the fir forests of the North-West Himalayas is in many respects in favor of the former. The slopes are less steep, so that you can walk up and down with the greatest ease, and they are not so rocky; the soil is deep and always moist, there is a conspicuous absence of under-growth (shrubs, bushes, herbaceous plants), and seedlings are found everywhere under any crop which is sufficiently advanced to shed seed copiously. The main conditions of natural reproduction by seed are therefore different in the two countries, and this should be borne in mind whenever fellings are made in the Himalayan fir forests. A certain strip of forest near the village of Hohwald was entirely cleared by the wind some years ago; it has receded itself, and now bears a dense young crop of fir and beech; such a result would only be seen in the Himalayas under exceptionally favorable circumstances, and even on the limestone soil of the Jura, where brambles and other plants grow up in a thick mass as soon as they receive sufficient light, such a spot would have to be planted up.

5. There are various

private owners, in the

valuable returns as hop

Schlestadt are well worth visiting, and Wasselonne is said to be as good a forest centre as can be found throughout the Vosges.

6. *Gérardmer*.—Gérardmer, in the Department of the Vosges, may be reached from Epinal by rail, or from Munster by diligence. The State forest, surrounding the fashionable watering-place of Gérardmer, contains 11,472 acres and is divided into eight working circles, of which six are treated by the regular method, while two are worked on the selection method owing to their being at a considerable altitude near the limit of forest vegetation. The rock is granite, and the altitude varies from 2,000 to 3,800 feet above sea-level.

7. The average composition of the forest is as follows:—Silver fir, 40 per cent; beech, 30; spruce fir, 20; other kinds, 10. Here as elsewhere, the two fir are the important species, and command the highest prices.

8. The average annual yield for the whole forest is not more than 50 cubic feet per acre, and the revenue for 1882 amounted to 7,448*l.*, or about 12*s.* 9*d.* per acre. Some of the working circles, however, show slightly better results than this; for instance, the eighth working circle, called *la Grande Montagne*, has an area of 1,868 acres. The annual yield of regeneration cuttings in the first block is based on volume, and it has been fixed at 84,768 cubic feet or about 45 cubic feet per acre. In this amount are included all windfalls and dead trees of three feet girth and over, and all trees of four feet girth and over removed in thinnings, selection fellings, &c., in the remaining blocks which have not yet reached their turn for reproduction. This leaves a small amount for thinning the smaller poles, windfalls, and dead trees under three feet girth throughout the working circle, but it cannot be estimated at more than 10 cubic feet per acre, making the total annual yield 55 cubic feet per acre. The revenue from this working circle for 1882 amounted to 1,367*l.*, or about 14*s.* 8*d.* per acre. The working circle of *la Grande Montagne* is well worth visiting owing to the regular distribution of age classes on the ground and favourable reproduction, but the yield and the revenue (if the figures given above, which were furnished by the local forest officer, fairly represent the average of a series of years) are remarkably small, and in this respect this forest compares unfavorably with other forests in the Vosges. The rotation on which this circle is worked is 144 years, divided into four periods of 36 years each, to each of which a block of an average area of 467 acres has been assigned. There are four Government saw mills in the locality, besides numerous private ones, and as a rule all the fir are cut up into planks on the spot. The total length of forest roads is about 42 miles. Gérardmer is well known to all forest officers who have passed through the school at Nancy, as every year the students are taken there to undergo a course of triangulation, and to be instructed in the working of saw mills, of which there are many kinds within the vicinity.

9. *Pontarlier*.—The communal forest of Pontarlier is situated near the town of that name on what is called the second plateau of the Jura Mountains consequently on the Jurassic limestone, and at an average altitude of 2,500 feet above the sea level. The first working circle has an area of 574 acres, and the average annual yield is about 70 cubic feet per acre, including thinnings and selection fellings. These limestone soils are rich, and there

is a great variety of undershrubs in this forest, including three species of *lonicera* and a herbaceous elder. If too much light is admitted on to the ground before the crop of young seedlings is thoroughly established, a dense crop of brambles springs up, chokes pre-existing seedlings, and renders natural reproduction slow and uncertain, if not altogether impossible. The third block of this working circle is chiefly remarkable for a regular and complete pole crop of silver fir sixty years old; the leafy canopy is complete, and there is scarcely any herbaceous vegetation on the ground. This portion of the forest is the more interesting as the reproduction cuttings which resulted in the present excellent crop were made in 1820 by M. Lorentz, one of the founders of modern French sylviculture and now Director-General of the Forest Administration.

10. One circle is worked on the selection method on account of the steepness of the slope, thus resembling in some of its features a Himalayan forest.

11. *La Fuvelle*.—This forest derives its name from *fue*, an old word for *epicea*, the spruce fir. It is situated on the third, or highest, plateau of the Jura mountains, at a mean altitude of 3,280 feet above sea level. The total area is 366 acres, and the forest is worked on a rotation of 140 years, which is divided into seven periods of 20 years each; there are consequently seven blocks containing on an average 52 acres each. The second period commenced in 1878, so it is in the second block that regeneration cuttings are now being made. In the first block, which was regenerated from 1858 to 1877, thinnings have already taken place once.

12. The crop consists of spruce and silver fir in almost equal proportions, and here it is the former which is the more valuable, the spruce having a value of about 7d. a cubic foot standing timber, whereas the silver fir is not worth more than 5d.

13. The soil is not deep, and the trees do not attain a greater length of timber than 80 feet; but for all that the forest has been so carefully organized and managed that the returns are remarkably good considering the great altitude. The average annual yield, taken from the figures for the last 25 years, amounts to 49,229 cubic feet, or about 135 cubic feet per acre; the average annual revenue during the period amounts to 925l., 2s. or 10s. 8d. per acre; while the expenditure has not been more than 40l. per annum, excluding the proper share of pay of the superior officers; this would not however raise it to any considerable extent, and there remains a handsome net annual revenue to the State.

14. In the second block, where reproduction fellings are now going on, we find numerous young seedlings of the two firs in the most promising condition; many of them existed on the ground before the primary cutting was made (*advanced growth*), and are now profiting by the extra amount of light given to them; the soil is not deep, and consequently there are no brambles or brushwood to interfere with reproduction, and the thin covering of moss on the ground permits the seed to germinate with great facility. The crop is aged from 140 to 150 years, as shown by the annual rings, and the trees have a mean girth of 6 feet at a height of 5 feet above the ground.

15. The third block shows a dense crop of tall timber, with much young growth of various sizes underneath; here and there the wind has blown down some of the taller trees, but generally speaking, the forest of *la Fuvelle* seems to be singularly free from the ravages of the wind. This is not the case with all forests in the locality, as there is a forest higher up the valley, where 5,000 trees were blown down in a single day, stopping all fellings for two years, greatly interfering with the nice calculations of the annual yield, and of course seriously compromising reproduction, for it is not every forest where one may expect such a favourable issue as that mentioned under the forest of Straaburg.

16. In the fourth and fifth blocks the trees are somewhat smaller, and the sixth and seventh have been already regenerated. Selection fellings are carried out in the third, fourth, and fifth blocks. In the seventh block we find a complete and regular young crop, 80 years old, growing up under the best possible conditions, with rather more spruce than silver fir. The average height of the poles is 85 feet, and their girth 4½ feet.

17. This most instructive forest is well worth a visit, as all the details of the organization project (which for this forest was prepared by M. C. Broilliard) can be the more readily appreciated by the beginner, as there is only one working circle, and the various age classes are very fairly represented.

18. *La grande Côte*.—The neighbouring forest of *La grande Côte* is situated on the other side of the valley at about the same altitude. It contains an area of 947 acres, and is worked on a rotation of 150 years; it forms one working circle, and is divided into five blocks, with five periods of 30 years each. The first period commenced in 1858, and is consequently approaching its term. The conditions of growth are much the same as in *la Fuvelle*.

19. The average annual yield, from the returns of the last 25 years, amounted to 104,636 cubic feet, or about 110 cubic feet per acre, and the gross annual revenue has amounted on an average to 1,970l., or about 2l. 1s. 7d. per acre, while the expenditure—omitting as before the pay of the superior officers—has not exceeded 81l. per annum.

20. *Levier*.—The forest of *Levier* is situated on the gentle slopes which descend from the second plateau of the Jura to the first plateau. It is distant about 18 miles from Pontarlier, and is in the conservatorship of Besançon and the department of the Doubs. The mean altitude may be put down at 2,500 feet above sea level.

21. The geological formation is the Jurassic lime-stone.

22. The area of the forest is 6,784 acres, and it is divided into eight working circles, and the transitional rotations adopted in them vary from 80 to 120 years; but when the forest has been

finally recognized as high forest, worked by the regular method of thinnings, the rotation will be uniform and fixed at 100 years. There will also be a smaller number of working circles.

23. As an instance of the present organization of the forest, we may take the second working circle called *Grand Jura Ouest*. The area is 622 acres, the rotation is 100 years, and there are five blocks, with five periods of 20 years each. The annual yield of the principal outtings is drawn from the second block, together with some old trees remaining in the first block, and it has been fixed at 44,233 cubic feet. In the third and fourth blocks selection fellings are made, and they extend over one-fourth of the area every year; in the first and fifth blocks improvement cuttings are made over about one-tenth of the area every year, so that any one part is re-visited every four years in the first and every ten years in the second case.

24. The following figures have been compiled from an elaborate return furnished through the kindness of M. Carlot, the Inspector of Forests at Pontarlier, and, as they embrace a period of two-and-twenty years, they may be relied upon as correct and adapted to show the true financial state of one of the best State forests in France.

Average of the 32 years, 1861 to 1888, inclusive.

Annual yield of all fellings ... 1,125,186 cubic feet.

Value of this yield (gross revenue) ... 22,332

Expenditure (not including a share of the pay of superior officers) ... 468

Reducing this to the acre, we find that the annual yield amounts to 166 cubic feet, and the gross revenue to 3l. 6s. 1d., a result probably unequalled in any other forest in France. If we allow a large margin for the proper share of the pay of superior officers, we shall find that the average net annual income to the State amounts to *three guineas an acre*.

25. The crop consists almost entirely of silver fir, which, in this forest, attains its finest dimensions as the following measurements will show:—One tree was 13 feet in girth, at 5 feet from the ground, and was 155 feet long, taking in all that could be sawn. Another tree, blown down by the wind, measured 146 feet long, and, roughly squared at the base, girthed 10 feet. Many trees standing had a girth of 10 feet and over, and as a rule logs are drawn out of the forest 80 to 120 feet long. There are large steam saw mills in the vicinity of the forest, and these logs are drawn out by bullocks in their entirety, so that they can be sawn up to any required scantling. In the Vosges the logs are scarcely ever more than 13 feet long, as that is the usual length of the planks required for the market. There is thus in the Vosges forests very little damage done to the young crops, whereas in the forest of *Levier* the injury caused to young saplings and seedlings is enormous. It is especially at corners and turns in the road that the chief mischief is done, for as the log sweeps round, it smashes and destroys all the young trees with which it comes in contact.

26. The wind is the most dangerous element the forest officer has to contend with on this exposed plateau of the Juras. In the eighth working circle a large space, containing over 200 trees, was cleared by the wind in 1880, and the soil is now covered with turf and brambles. The crop was a dense high forest, about 170 years old. There were very few seedlings underneath, and now the whole area will have to be planted up with some difficulty, as silver fir does not come up well in the open. Even in conducting the regular cuttings great prudence has to be exercised, as, if too much light is admitted, the rich soil gives birth to a dense mass of brambles and herbs, which greatly impede the growth of seedlings if they do not entirely prevent it. Similar results, only on an exaggerated scale, may be seen in the silver fir forests of the North-West Himalaya, where, even under the densest canopy of mature trees, the undergrowth of herbaceous plants is so thick that seedlings establish themselves with difficulty, and the evil is made worse when more light is admitted.

27. Forest officers on leave from India should be recommended to pay a visit to the forest of *Levier*, as there is much to be learnt in every way from a careful inspection of this splendid forest; and if ever a Forest School is created in England, and the students are taken abroad to study continental methods of forestry, they would do well to direct their steps to Pontarlier and make themselves thoroughly acquainted with the silver fir forests of the second plateau of the Jura mountains.

28. *La Joux*.—The forest of *La Joux* touches the forest of *Levier* on the south, and in reality forms one continuous forest, only it is in a different department and in a different conservatorship. Its area is 6,543 acres, and it has a mean altitude of 2,625 feet above sea level. The forest is divided into five working circles as follows:—

| NAME. | Area in Acres. | Rotation Years. | ANNUAL YIELD. | | Remarks. |
|-------------------|----------------|-----------------|--------------------|--------------------|---|
| | | | Total. | Per Acre. | |
| | | | <i>Cubic Feet.</i> | <i>Cubic Feet.</i> | |
| Northern ... | 1,589 | 100 | 120,888 | 76 | The annual yield is that of the regeneration cuttings alone in the first and fifth block. |
| North-Eastern ... | 809 | 160 | 78,797 | 88 | |
| Eastern ... | 1,297 | 140 | 143,470 | 116 | |
| Southern ... | 1,213 | 140 | 108,313 | 90 | |
| Western ... | 1,605 | 140 | 142,198 | 89 | |
| Total ... | 6,543 | | 594,466 | 90.8 | |

29. To this annual yield of 91 cubic feet from the regeneration cuttings in the first and fifth blocks, we must add that which

results from thinning and selection fallings in the other three blocks. This may be estimated at 45 cubic feet, and we thus obtain a total annual yield of 136 cubic feet per acre.

30. The gross total revenue is now 16,000*l.*, or about 2*l.* 8*s.* 11*d.* per acre. It was formerly as high as 20,000*l.*, but the price of wood has gone down. The expenditure may be estimated at 800*l.*, or about 8*s.* 6*d.* an acre, leaving a handsome net income to the State, though it does not come up to the forest of Levier. The conditions of climate, aspect, growth, export, &c., are very much the same in the two forests, and it is not easy to understand why there should be so much difference in the revenue and in the yield.

31. *La Fresse*.—The forest of *La Fresse* adjoins the forest of *La Four* with an area of 2,820 acres. The crop consists principally of silver fir, but this tree does not attain the same dimensions here as in the forest of Levier, and the yield and the revenue are much less.

32. *Chamonix*.—The communal forest of Chamonix is situated both sides of the valley and chiefly between that place and Argentiere. The area is 2,780 acres. It is composed almost entirely of spruce, fir, and larch, and is worked by the selection method. Any other method of treatment would be here quite out of the question. The high parts of the forest are at the limit of tree vegetation, and the extreme rigour of the climate, combined with steep and rocky slopes, render reproduction difficult and uncertain; seedlings of larch and spruce, however, are not wanting wherever the light and the soil are suitable. There are but few large trees remaining in the forest at the present time, and the spruce seldom attains a larger girth than 6 feet, while the larch is found 8 or 9 feet in girth.

33. The annual yield was estimated at 35,300 cubic feet, or about 13 cubic feet per acre, but these figures must be accepted with some reserve; still there is no doubt that the yield of forests so high up cannot be compared with that of forests lower down, and on more fertile soils. It may be as well to state that the revenue of this forest cannot be given, as the timber cut annually is divided among the inhabitants of Chamonix, who either sell their share or use it up for their own requirements. The value of the cubic foot of spruce standing in the forest is about three-pence, while that of the larch is almost double.

FOREST PROGRESS. REPORT FOR BENGAL, 1881-82.

THE area of reserved forests in Bengal was, at the close of the year, 4,236 square miles, or an increase of 825 square miles during the year under review, and the Conservator is to be congratulated on the fact, that in his own words, he has very nearly come to an end of the first great work to be done by a Forest Department, on its institution, namely, the demarcation and settlement of the forest areas actually available. The Fengallia range near Darjeeling, extending over 60 square miles, was demarcated by Mr. Gamble, who thus describes it: "These forests contain, with the exception of a small area of *Pinus longifolia* forests in the valley of the Great Rangit, the only areas covered with the coniferous trees in Bengal Forest Circle. The conifers which are found in them are of four species, the silver fir (*Abies Webbiana*), the Indian hemlock spruce (*A. dumosa*) the blue juniper (*Juniperus recurva*), and the yew (*Taxus baccata*). The silver fir forms large forests, almost pure, on the slopes of Sandukpho and Suburkam, from an elevation of 12,000 feet down to 10,000 feet, at which point it is replaced by the hemlock spruce, which is also gregarious, but to a less extent than the silver fir, being often mixed with rhododendrons, birches, and other trees. The blue juniper is only found occasionally in single specimens, but is valuable on account of its leaves, which are much used to burn in the Buddhist temples. The yew, which occurs at the lowest elevation of the four, is not uncommon on Tonglu, where very large trees, reaching even 20 feet in girth, are occasionally met with.

"The common oak in these forests is the *Quercus pachyphylla*, which is frequent and of large size and straight growth. Both red and white magnolia (*Camp*) are also common."

We are glad to see that steps are likely to be taken shortly for placing the private forests in the Chota Nagpore Division, with the approval of the owners, under systematic management, and we would recommend Conservators in other circles, where private forests are numerous, to consider whether similar steps cannot be taken in their respective provinces.

Referring to the semidari forests in the Hazaribagh district, the Conservator states that it is a noticeable fact that almost throughout Hazaribagh, the villagers, while grazing over or cutting the said forest, have the habit of usually leaving some small area covered with sal poles sufficient to supply them with building materials, and that the resources of these village reserves are carefully husbanded, and cutting only allowed under self-imposed conditions. This practice shows that the people are quite alive to the necessity for careful management, and that they will be quite capable of understanding the objects with which an attempt to introduce forest conservancy is made.

On Mr. Gamble's proposals for the formation of village forests, the Local Government makes the following favourable comments:—

"The importance of this question and its bearing on the economic condition of large portions of these provinces, cannot be exaggerated. In addition to the beneficial climatic effects which groves and forests are now admitted to produce, it is evident that the provision in many districts of a cheap and convenient supply of

firewood means the utilization for agricultural purposes of the vast quantities of manure which are now used for fuel. From the employment of manure for agricultural purposes, an improvement in the harvest yield might be confidently expected, not to speak of the introduction of more valuable staples. We have now in Bengal reserved forests for the supply of large timber, but in situations more or less remote, where population is scanty and communications bad; we have protected forests managed by Government in the interests of the public; but we have none of the third class of forests contemplated by the Act—village forests for the supply of fuel only. It is time that some beginning should be made to supply the want, and the Lieutenant-Governor will be glad to receive from the Forest Department or from local officers some proposals on the point."

The protection from fire of 970 square miles were attempted, but the season was not a favourable one, and 7 per cent of the area was burnt. A remark is made in the review of the Government of India to the effect that the data given in form No. 51 differ widely from those given in the body of the report, and that in future years from No. 51 should show only the areas regarding which special measures have been taken to keep out fires. It is most important that this should be observed, as if in one province evergreen forests are shown, and in the next excluded, no fair comparison can be made of the cost of protection per acre. That fires in Bengal can be very disastrous, is unquestionable, as it appears that the fire which occurred in compartment No. 9 of the Ranbul block, Darjeeling Division, killed nearly every tree in it, and left the ground bare with tall dry stems standing up in it. These are now being cut as fuel, and the compartment is being planted up. As a proof of the good effected by fire protection, we quote para. 114 of the report:

"In this place it is well to refer to the very marked improvement which the forests of the division (Kurseong), have made in the last ten years.

"The Officiating Inspector General visited the division in the Conservator's company, and most especially in the sal producing blocks of the Dulka jhar, the Sivoke forest, the Mahanadi forest, and the Marjha forest was the improvement noticed. Sal forests, that a few years back consisted of small thin poles with much grass, are now densely stocked with tall young trees, and the grass is rapidly disappearing.

"Savannahs that formerly showed scarcely a tree are filling up and no longer deserve that name. Much of this is doubtless due to fire protection, but still more to general protection from cuttings, and especially to demarcation and good boundaries."

There are 1,215 acres of regular plantations which do not include such "cultural" operations as supplying blanks in natural forests, or re-stocking cleared areas, and it would be as well for all Forest Circles to adhere to this rule as far as possible.

The largest plantation is in Bamunpokri in the Kurseong Division, and it is reported to be doing well.

The Sunderbun is the great revenue-producing division of the Circle, with a revenue of over 3 lakhs for the year under review, whilst the majority of the other divisions show small deficits, which it is anticipated will in a few years be changed into surpluses.

The revenue of the circle is derived from the following sources:

| | Ra. |
|--------------------------------|----------|
| Timber | 3,31,000 |
| Fuel | 1,60,000 |
| Bamboo and other minor produce | 1,00,000 |
| Miscellaneous | 43,000 |
| Total Ra. | 6,34,000 |

More than a lakh of rupees was received on *Sundri* wood (*Heritiera littoralis*).

In the "Manual of Indian Timbers," a new and excellent work completed by Mr. Gamble in the year we are reviewing, we find the qualities of this timber, and the character of the forest it forms thus described: "Sundri wood is durable; it is heavy and does not float, and is extremely tough. It is used for a great variety of purposes, such as beams, buggy shafts, planking, posts, furniture, firewood; but chiefly in boat-building, for which purpose it is very extensively used in Calcutta, and particularly in the Government Dockyard at Kidderpore. It is the chief timber of Sunderbun forests. Its reproduction is most favourable.

"On all lands flooded by ordinary flood-tide, a new growth of jungle springs up immediately, but on land ordinarily above high-water mark it only establishes itself by slow degrees. It soon spreads itself on newly-formed islands on the sea edge of the forests. The roots of the *Sundri* do not penetrate deep into the ground, but spread laterally 2 to 3 feet below the surface, sending out perpendicular tough shoots, which stand from 3 to 15 inches in height all round the parent stem, and when there are many trees close together, walking through a *Sundri* forest is very much like finding one's way among a fine growth of inverted tent pegs."

The Sunderbuns, besides timber, furnishes a considerable quantity of minor forest produce, and nearly half a lakh of revenue is obtained from *galpatta* (leaves of *phenix paludosa*) used for making ropes and for thatching. Another curious item of revenue in this division is the Ra. 2,000 odd received for shells.

Tigers appear to be increasing in these swampy forests, and no less than 161 wood-cutters were carried off by man-eaters during the year, or more by 70 than the number for the preceding years.—*Indian Forester*.

THE GARDEN.

THE GARDEN BALSAM.

THIS favourite annual is one of the best we have for brightening up our gardens in the rains, and during the flowerless months in the beginning of the cold season. The wild species, *Impatiens Balsamina*, from which our garden varieties have sprung, is a native of India, and is principally found growing in damp, shady places in the lower Himalayan valleys. The wild plant has a beauty of its own, but from a florist's point of view it is not to be compared with the variously colored, double-flowering cultivated varieties. It is grown in most of the European and Native gardens throughout the country, but unless the plants have been raised from imported seeds, the varieties met with are not far removed from the wild species. It is possible to raise plants from Indian grown seed with flowers little inferior to those of the best *Camellia* and *Carnation* flowered varieties of European nurserymen's catalogues, and as raising one's own seed is a pleasing and profitable occupation, I shall, further on, describe the most certain method of securing a strain of good acclimatized balsams. The coarse weedy strains will exist without any care or trouble, but in order to have well grown plants of good varieties in flower from July until November, a little attention has to be paid in selecting the dates for sowing, and also to their treatment during the progress of growth.

The first sowing should be made in the beginning of June, and continued every fortnight until the beginning of September. The seed pots should be kept under the shade of a tree, or covered by mats or any suitable shading material until the seeds germinate. As soon as they have germinated, shade should be gradually withdrawn until the seedlings are able to stand full exposure to the sun. When the seedlings are two or three inches high, they should be potted singly into small pots, and again shaded for a day or two until they have made fresh roots. In the course of ten days or a fortnight they will be ready for a shift into a larger sized pot, and the same process should be continued until the flower buds begin to appear. In order to have good specimen plants, three shifts should be given during their progress of growth, but if time cannot be spared, and if the proper sizes of flower pots are not to be had, only two shifts need be given. It is a good plan to see that the soil does not neglect to shift them as soon as ready, and that he uses the proper sized pot. As a rule, when left to his own devices, he will transplant them from the seed pot into one of the largest he can lay hold of. The result of his treatment is tall weedy plants or total loss from sourness of soil and damp. The gradual transplantation from a small-sized pot into a larger is a very important matter, and should never be neglected when specimen plants are desired. The soil should be light and rich, and the pots thoroughly drained. I find the following to be a very suitable mixture of soil, viz., one part loam, one part old cow or stable manure, one part leaf mould, and one part sharp river sand. Water liberally, but take care that the soil in the pots never becomes sour owing to defective drainage.

In order to save seeds from the *Camellia* and *Carnation* flowered varieties sent out to this country by European nurserymen, the sowings made from the beginning to the middle of July, should be especially looked after. Sowings made previous to that time generally fail to produce seed, owing to damp, and those made later fail owing to cold. When the plants are densely branched, thin out the lateral shoots, so as to allow of all those remaining to stand clear of each other. If the strain is a good one, the flowers will be very double, hence many may fail to produce seed, and those that do, only produce it in small quantities. As they seldom all fail to produce a few seed pods in October and November, a few ripe seeds are generally obtainable. These should be carefully stored, and kept until the following July, and sown between the beginning and middle of that month. The flowers from the acclimatized seed of the first season are invariably of poor quality. Many are single and semi-double, and a few double, but inferior to the flowers of the previous season, grown from imported seed. The best double flowering plants should be selected as seed-bearing stock, and kept as far as possible from the plants with single and semi-double flowers. If selection and isolation is carefully attended to, it will be found that the proportion of good double flowers will increase yearly, and in the fourth season out of hundreds of plants scarcely any single or semi-double flowers will be met with. The strain of acclimatized balsams you thus secure will seed freely, and possess flowers nearly of equal merit to those of the best imported varieties. They are also much hardier and not so subject to damp off during periods of excessive rainfall.

MINERALOGY.

On Laterite and other Manganese Ore occurring at Gosulpoore, Jubbulpore District, by F. R. MALLER, F.G.S., Geological Survey of India.

IN a previous volume of the Records (1) some account is given of the manganese ore at Gosulpoore, which was visited by the Superintendent of the Geological Survey in 1879. The sections then available for examination were very poor indeed, but, judging

from what could be seen, Mr. Medlicott thought that a large supply of the ore could probably be depended on. The following year a shaft was sunk with a view of testing the richness of the deposit. When this had reached a depth of 40 feet, the engineer in charge reported "that all trace of the ore was lost at a depth of nine feet from the surface, at which depth a yellow subsoil, resembling ochre, was entered; that about 1½ cubic feet of ore were obtained, and even this small quantity of rather an inferior quality, that in consequence I recommended and discontinued operations." As this discouraging result was at variance with the hope previously entertained of a considerable supply, I was directed to take the opportunity, while in the neighbourhood recently, of visiting the locality and seeing how the discrepancy was to be explained.

The shaft is dug on the site of the pre-existing holes examined by Mr. Medlicott, from which the ore had been extracted for use in glass-making at Murwara and elsewhere. The section comprises—

| | Feet. |
|--|--------|
| a. Laterite | 4 to 5 |
| b. Manganese ore | 9 ½ |
| c. Laterite containing some nodules of manganese ore, about | 6 |
| d. Disintegrated quartz schist dipping at a high angle (to bottom of shaft) | 7 |

The manganese ore b, which, as mentioned in the previous notice (2) is pyrolusite mixed with some psilomelane, occurs in the form of irregular spongy nodules varying in size from a fraction of an inch to several inches diameter, and averaging perhaps half an inch to 1 or 2 inches. These seem to constitute an irregular layer, which is 2 feet thick, or rather more, at the shaft. It is exposed in two or three other places within a length of 20 feet. The level varies somewhat even in this short distance, and, as pointed out by Mr. Medlicott, the ore found in the village well, 120 yards to the east, is at a lower level than that at the shaft. This difference in, I think, to be ascribed to the laterite (including the ore) having been deposited on an irregularly denuded floor of Bijawar rocks.

There is little or no laterite of the ordinary (ferruginous) type included in the manganese stratum, and the separation between this stratum and the laterite above is tolerably well defined; that between the manganese and the laterite below is not so well marked, the laterite containing occasional nodules of pyrolusite through it. The laterite above and below the ore looks somewhat like detrital variety, but experience elsewhere has led me to believe that the rock laterite (3) has a tendency to disintegrate into a mass of irregular nodular fragments, which bear a very close resemblance to the detrital form. Taking into account that no distinctly foreign matter is visible in the rock in question; that undoubted rock laterite occurs close by; and that the manganese ore is pyrolusite, not psilomelane (a point to which I shall allude again), I do not think there can be any reasonable doubt that the laterite, inclusive of the ore, is rock laterite not detrital. Such is the view which Mr. Medlicott also took: "This laterite is of the older type; at least in the exposed sections I could not detect any palpable debris, which generally characterises the secondary or detrital laterite. It is therefore presumable that the lumps of ore are innate, and that the manganese is an integral component of the laterite in this position." (4)

With reference to the original source from which the manganese was derived, it is, I think, scarcely open to doubt that it is to be sought in the strong band of manganeseiferous micaceous iron, which outcrops along the southern side of the Lora range and again at Gosulpoore (5). But, as I said in the preceding paper, the manganese in this ore occurs mainly, if not entirely, in the form of psilomelane, while manganese of the laterite is mainly pyrolusite. The latter, therefore, cannot be the result of mere mechanical degradation and transport, unless it be supposed that the nodules in which the ore occurs are pebbles, originally of one mineral which has subsequently been changed into another. This mode of origin is rendered very unlikely by the absence of any other recognisable debris in the manganese stratum.

If the latter be not a mechanical deposit, it must be a mechanical one. Carbonate of manganese being, like carbonate of iron, soluble in water holding carbonic acid in solution, the former metal is capable of being leached out and re-deposited in the same, or nearly the same, way as the latter (6). During the deposition of the main stratum of manganese ore, the water appears to have held little but manganese carbonate in solution, while at the time the laterite below was formed, ferrous carbonate was the chief substance dissolved, but with some manganous salt, the manganese subsequently separating itself into nodules by segregatory action. Specimens may be obtained consisting in part of ordinary laterite, and partly of manganese oxide.

The occurrence of this manganese laterite, interbedded with ordinary ferruginous laterite, furnishes, I think, strong evidence in favour of the view as to the origin of the latter which I have advocated in a former paper (7) namely, that laterite is (in as far as the iron is concerned) a chemical deposit due to the leaching out and re-deposition of iron through the agency of decaying

(2) *Ibid.*, p. 103.

(3) By 'rock laterite' I mean the first form of laterite mentioned on page 117. The term is no doubt open to criticism, but is convenient and serves to avoid circumlocution.

(4) Vol. XII, page 89.

(5) Page 102.

(6) *Vide* Vol. XIV, page 145.(7) *Ibid.*, page 139.

and the carbonic acid produced by its decomposition. I of course am speaking of the first only of the three forms of laterite which I believe are now generally recognised, viz.—

- 1st.—Laterite due to deposition, and excluding the 3rd form.
- 2nd.—Laterite due to the alteration of other rocks *in situ* (8).
- 3rd.—Detrital laterite due to the denudation and re-deposition of the 1st or 2nd form.

With reference to the amount of manganese ore obtainable, it is not easy to form any decided opinion. I think, however, that there is a fair chance of the layer being somewhat extensive, although very likely subject to much irregularity in level and the amount of overburden covering it, and perhaps, in thickness also. When there is a demand for the mineral, the bed might be followed from the present diggings, and the superincumbent laterite utilised for road metal on the Deccan road which passes close by.

It will have been seen that the reason why so little ore was obtained from the shaft was that the latter passes through the manganese stratum into quartz schist below it. The shaft, indeed, merely exposed the thickness of the bed, but proved nothing as to its lateral extension.

In the preceding paper I have pointed out that a considerable quantity of pisolomelane occurs with the manganiferous micaceous iron at Gosnupore. If the latter were worked in connection with iron-making, the pisolomelane would be raised at the same time, and available as an ore of manganese. On assay it yielded 83.20 per cent of available peroxide, or about the same amount as the lateritic pyrolusite. From both sources combined, it may be reasonably hoped that a considerable supply of ore will be procurable when there is a demand for it.

Further Notes on the Umaria Coal-field (South Rewah Gondwana Basin); by Theo. W. H. HUGHES, A.R.S.M., F.G.S., Geological Survey of India.

In my notes of last year on the Umaria coal-field were embodied the general results inferable from the evidence afforded by the preliminary experiments carried out under the management of the Rewah State; that coaly matter occurred in abundance; that it lay at a shallow depth from the surface over a proved area of 1½ square miles; that it thickened to the deep; that the gradient was low and advantageous for working; and that the quality of the coal at the outcrop was encouraging.

The promise was a fair one, and from the exceptionally commanding geographical position of the field, it required small advocacy to show that if the expectations based on the introductory enquiries were confirmed, a splendid reserve of coal had been established. I am happy to say that Captain Barr, the Political Agent of Rewah, has keenly appreciated the exigencies of the case, and his further sanction has been obtained for carrying out such trials as shall set at rest any apprehensions that prudence may give rise to.

I confess that I have little or no misgiving as to the worth of the Umaria and the adjacent Johilla fields, and I have belief enough in my opinion to give it expression. But I admit the necessity of verification; and, in view of the important issues dependent upon the true practical estimate of these fields, I strongly commend the course that had been suggested of reducing to its narrowest limits the margin of uncertainty regarding the nature, quality, and permanency of their seams.

To achieve this object it was determined that the coal should be approached under the ordinary conditions of approved mining. There were two plans open for adoption, either to drive an incline from the outcrop, or to sink a shaft to the seam. The second method was preferred, as being in every sense more workman-like, and as affording more scope for efficiently dealing with an influx of water; and on the 11th March 1883, a pit of 10 feet internal diameter was commenced under the charge of Mr. Thomas Forster, M.E.

The position of the pit is near No. 8 bore-hole, where Mr. Stewart struck coal at 93 feet from the surface and recorded the thickness of the seam as 10 feet. I had a strong wish to go further to the deep towards No. 9 bore-hole, but I was deterred by the dread of water, and the possibly heavy outlay that would have to be incurred for pumping machinery.

In an untried field it is always impossible to gauge the water difficulty, and I selected the spot for the trial shaft where I anticipated the least amount of inconvenience on this score. The choice has been up to the present justified by the results, for though the shaft is 40 feet deep, one workman occasionally bailing suffices to keep it dry. Should the pleasant expectation that this fact gives rise to be strengthened by further experience, I would certainly recommend another pit near No. 9 bore-hole being put down. In the future development of the field, it would act as a ventilation channel; and in the initiatory stage it would yield another point where the quality of the coal might be judged.

According to the journals of last year, two seams measuring respectively 10 feet and 6 feet were passed through in No. 9 boring, and I remember that the coal brought up in the sludger was very clean and bright.—Records of the Geological Survey of India.

(8) Some examples of this form are noticed in the preceding paper, page 97, 98.

TOBACCO.

CULTIVATION AND MANUFACTURE OF TOBACCO.

Memorandum on Tobacco Cultivation and Curing at Gazipur in contrast with the French system described by Kumar Gozendra Narayan, Jr., of Kuch Behar, in his Memorandum, page 19 of his Report on the Cultivation and Manufacture of Tobacco in France, 1881.

Shelter for field.—The tobacco fields are usually sheltered from the hot west winds by a high crop on that side, or, in the absence of this, by sowing a line of castor-oil plants or any other fast and high-growing crop. The cultivation commences in July, in France in October.

Rotation of crops.—We follow the American system, and tobacco is grown on the same land only once, or on rich land twice, in three years. The land usually lies fallow the third year, or should do, and in America a crop of oats is often sown, which crop is ploughed into the land just as the ears commence to form. In France tobacco is grown on the same land only once in in from five to seven years.

Manure.—The manure at Gazipur and Poona consists principally of cowdung and vegetable manure, such as leaves, indigo scut, &c.; at Gazipur a good deal of night-soil and poppy trash. The land is manured yearly.

Soil.—Lands suitable for sugarcane and poppy are selected as being the richest. The land is ploughed from commencement of rains to the time of planting, or earlier if feasible.

Seed-bed.—A piece of good high land is selected, well ploughed, cleaned and manured with good old manure (low ground would swamp). The ground, when soil has become well pulverised, is now marked off into beds four feet broad and running the whole length of the ground. The bed is slightly raised in the centre as a protection against heavy rain. A small ditch is out between the beds to drain off the rain. Tatties made of straw or arhar twigs are put over the beds, and are raised three feet from the ground. The seed is sown in July, and the second sowing is made in August in case of accidents. The seed is sown at a different season to the French season, and differs in soil, and in not having a stony hard under-surface which would not drain off well.

Sowing in seed-beds.—Two table-spoonfuls of seed are sown over 100 square feet of seed-beds. It is sown mixed with ashes.

It is not left to germinate before being sown as in France (this plan has not yet been tried). It is sown by a man who stands in the ditch running between the seed-beds. After the seed is sown, the bed is beaten down gently with a plank, or the naked feet of coolies. The seed germinates in eight days. The land is kept clean from weeds. The tatties are kept on for at least a fortnight. They are left gradually, that is to say, they are first taken off for a few hours daily, in the morning and evening and at night, till the young plants get accustomed to the sun. They are a protection to the plants from the sun and also from heavy rain which often washes out the earth from the roots of unprotected seedlings. This is also done in France.

The tatties must not be left on until the young plants are transplanted, or else the plants will be weak and unable to bear the sun.

Transplanting.—The land having been well ploughed and cleaned from the middle of June to the middle of August, is smoothed over with a *henga* (harrow), and the young plants being now large enough, they are transplanted when the leaves are not quite the size of a rupee. A cloudy or rainy afternoon is selected for the planting (the afternoon is better than the morning, as it gives the plants the whole night in which to take hold).

The field is either marked out beforehand, by means of a long rope laid on the field, along and on which a few coolies are made to walk, and which leaves a clearly-defined line marked on the field; these lines are made first down the field and then across, each line being the same distance apart, or else a lighter rope marked with knots is thus laid on the field at the time of planting, and a plant is put in opposite each knot. It is very necessary for facilitating the after working of the tobacco that the plants should be equidistant from each other. In rich land the plants are put three feet apart. In poorer soils they are only two feet and two and-a-half feet apart. No plants whose stems have become at all hard should be planted; they will certainly be stunted. Grubs should be looked for in the roots and stems, and all affected plants thrown away. If the ground is hard and clayey, it is desirable to stir the earth with a *therpes* a little round the young plants three or four days after the planting.

Hoing and earthing up.—The land is usually hoed about 10 days after planting. When the plants are from a foot to 1½ feet high, the earth is thrown up round the roots of each plant. This

is the same process apparently as that described as ridging by Kumar Gozondra Narayan, Jr., in his memorandum.

Irrigation.—This is carried on whenever, from the appearance of the plants, it is required. The ground is hoed and the plants earthed up after each watering until the plants become too big to allow of men working in the field.

Tapping and pulling off suckers.—When the plants are about 3 feet high, or, if weakly-looking, 2 feet, the top shoot is plucked off (this shoot is plucked off, directly it makes its appearance in small or sickly plants), also the lower leaves which are dirty and dragged, and from 7 to 14 leaves are left, according to the strength and growth of the plant, the principal object being to get a few large and well-developed leaves in preference to a quantity of small ones. The side shoots or suckers are plucked off the instant they appear, and are left on the field for manure.

Frenching and grubs in the plants.—In frenching, the leaf puckers up and is only fit for the native market. If a grub be found in a large plant, it should be cut out with all the affected part and all the portion of the plant above it—a side shoot may be allowed to grow which will give a fairly good plant.

Signs of maturing.—Tobacco ripens in about three months' time. It is out during the months of November, December, January, February, to the middle of March. A ripe leaf has yellow spots on it. It has a crumpled look, and if bent between the finger and thumb will break.

The cutting and drying of the tobacco as described in Kumar Gozondra Narayan's memorandum, pages 22 and 23, is totally different to the system pursued at Gazipur. Does not Kumar Gozondra Narayan's memorandum refer to cutting and curing for cigar tobacco only?

Cutting or harvesting.—The cutting commences directly there are sufficient plants ripe in a field to fill a curing barn. The plants are cut off bodily at the stem just below the lowest leaves of the plant. The plants, when cut, are left lying with their butts towards the sun in the field to wilt. The time a plant takes to wilt depends on the heat of the sun. Usually half-an-hour is sufficient. When wilted the plants are either carried or carted to the curing barn. There they are spiked on split bamboos. In the French system the leaves are plucked off the stem and hung in the barn on strings.

Spiking and hanging in the barn.—Each coolie is provided with an iron spike which he fixes like a spear head on to the bamboo stick, he then takes a plant of tobacco in his hand fixing first the other end of the stick into a hole in a block of wood provided for the purpose which he holds between his toes. The plant is placed with the butt on the spike about 5 or 6 inches from the end and the plant forced down over the spike on to the stick. From 6 to 10 plants according to size are hung on one stick which is 4 feet long. These sticks are then hung in the barn; the stick should be hung so that the leaves may touch each other slightly, but should not press against each other. The barn is fitted up with a scaffolding of bamboos. The bamboos are 3 feet 6 inches apart and 4 feet above each other, the lowest tier of bamboos being 6 feet at least from the ground (where the tobacco is intended to be cured by fire). The barn is provided with as many doors as possible, those on the west side being made as air-tight as possible. Ventilators in the roof made to open and shut are advantageous. Rooms can be made any size. A room from 35 to 40 feet high and 30 yards long by 15 yards broad is preferable, as it can be filled rapidly, and will hold sufficient tobacco to cure well.

Curing and Drying.—When the barn is full (it should be filled as rapidly as possible in order to prevent the tobacco drying out in hanging), all the doors are closed, and also the ventilators if any. It is left for two or three days. The planter can now tell whether the tobacco is drying up too rapidly or not fast enough. If the tails of the leaves curl up and break when handled, it shows that the tobacco is going up too fast; on the other hand if there is a sour smell in the room and the plants sweat, the tobacco requires air and perhaps fire. In the first case the doors and ventilators are still kept closed and fires are lighted in different parts of the room, or if the house is filled with flues (which are preferable to open fires) hot air is carried through the room in the flues. The temperature will probably be raised 80° Fahrenheit, but this can only be told by experience. The tobacco must be carefully watched, and if drying too fast, the temperature lowered and water sprinkled on the floor. Raising the temperature causes the tobacco to sweat and the moisture thus created in the house makes the colour run in the leaves. The leaves should turn gradually yellow and then brown. If dried too rapidly it retains its original green colour. If it is intended to cure golden leaf the temperature is raised to 140° Fahrenheit or higher at the stage in which the tobacco has changed to a yellow, but this curing cannot be attempted in a hot climate, except by an experienced curer. Golden leaf realises double the price the dark leaf does. The plants should originally all be in the same stages of ripeness to ensure success in bright or golden leaf curing. In the above, curing in a hot dry climate like Gazipur is referred to; in Tirhoot in mild weather tobacco can be cured without any fire. This process will now be described. If, as in the second case stated above, after two or three days hanging in the barn tobacco feels soft, then there is a sour smell in the room and the plants may or may not sweat, then all the doors and ventilators should be opened and kept so until the sour smell is gone and the sweating has stopped; if that is not effectual then fires must be lighted. The curer must now be guided by the weather, and must carefully watch the tobacco. If the tips of the leaves begin to curl, it is going too fast and the doors must be shut during the day and opened only at night to allow the cold air to circulate through the room, the main object being to make the tobacco dry up gradually to

yellow, and the greater part of it will turn reddish yellow called medium bright. The temperature must be regulated by the doors and ventilators. This air-curing makes a lighter brown than the firing process, and can only be adopted in a climate in which there is a certain amount of moisture in the air. If the tobacco sweats badly, doors and ventilators must be opened, and fires lighted, and a heat raised till it stops. Green tobacco is preferable to sweated. There is another process followed in some parts of America called sun-curing. In this process a scaffolding is erected under the shade of a tree, and after the plants are hung up, the whole is covered around and on the top with straw. The straw is opened out when it is found necessary to quicken the drying. This style of curing is hardly adaptable to the plains of India.

Flues.—Flues are iron pipes, fitted up a little above the floor. The hot smoke carried through them finds its exit in a chimney at the end of the room. The fires are lighted in furnaces outside the building or just inside with the furnace opening outside. It has many advantages over the open fires, as no smoke stagnates in the room to taint the tobacco, and the risk of fire to the building is reduced to a minimum. The temperature can also be regulated better. For a room 30 yards long by 15 yards broad, you would require three furnaces; these furnaces are built of pukka masonry. The pipes should be 15 inches in diameter. The pipes should be arranged so as to spread the heat equally through the room. Tobacco should not be hung directly over the furnace as the heat would dry it up too rapidly.

The higher the barn is the better it is for curing purposes. The highest tobacco in a room is usually the best colour, if you have a thick roof, otherwise the centre is the best.

Bulking, sorting, and banding.—The tobacco is generally cured, so far as its colour goes, in a fortnight or three weeks. It is left to hang through the hot weather in the barns, as the heat makes it too dry to handle. Early tobacco may be ready to bulk down in the Christmas rains. No tobacco should be bulked until the sap is entirely dried out. This can be seen by breaking the stem of the leaf. If bulked with sap in it, it will rot.

Directly the rains commence in June and the tobacco has become soft and pliable, it is bulked down in heaps in the curing-room in which it is hung. The heaps are raised some 8 inches off the ground by a small scaffolding made up of bamboos and stick, so that air can circulate underneath, and are covered over with straw or matting. The tobacco should not be bulked down in too moist a condition. The best order for bulking is when the tobacco is just soft enough to handle without breaking. If too soft it must be fired and allowed to come in order again. When all the tobacco is bulked down, the bulks must be opened and the leaves stripped from the stem and tied in "bands" or "bundles" with about 50 leaves in each band. The band is tied round with a leaf of tobacco tied round the upper ends of the leaves and tucked in at the centre of the bundle; these bands are now carried to the head barn or sorting-room. They are re-bulked here in the same way as before. When all the tobacco is in the sorting-room, the bulks are again opened and the bands being untied, the leaves must be sorted. They should be sorted into—1, long leaf dark; 2, short leaf dark; 3, long leaf bright; 4, short leaf bright; 5, lugs—that is, all torn or dirty and very small leaves, red and bright, being banded separately; and 6, green—six varieties in all. The sorting is most important and requires strict supervision. Care must be taken that the coolies do not make unnecessary breakage in handling the leaves. They should be tied in bands of from 15 to 20 leaves. These bands are again bulked and left in bulk till packed. The bright is divided into four varieties, should there be any golden leaf. Golden leaf is, pure yellow. In this case you have—1, bright long leaf (that is golden leaf); 2, bright short leaf; 3, medium bright long leaf; 4, medium bright short leaf. Lugs are often made into strips by taking out the thickest portion of the stem midrib; two-thirds is taken out one-third of the way from the tail of the leaf. It sometimes sells best in this form.

Packing.—The tobacco is packed in hogsheds made of thin staves. The hogsheds are made 4 feet in height, and about 3 feet in diameter for despatch to Europe, or else after the native custom in bales. The tobacco should be packed as dry as it can possibly be packed without breaking it. It is generally necessary to hang it again in a barn, the bands just slung across the stick, and fire it till sufficiently dry. If too dry, the doors may be left open at night when it will probably be found in the right order on the following morning. The bands are packed with the butts outwards and tails inwards. There are three lines in each row, two with their butts at the edge of the hogshed and tails meeting in the centre of the hogshed, and one in centre of the hogshed. The next row is commenced from the other side of the hogshed. When the hogshed is filled, it is pressed down with powerful screws, and refilled, till it can hold no more. It should contain 900lb. of leaf as nearly as possible.

G. CAINE.

WANTED, by the Local Government of British Burmah, a thoroughly practical Miner, to sink shafts and bore holes. Salary, Rs. 250, and quarters. Only practical men need apply. Engagement for one year certain.

Applications to be forwarded to

D. MACKENZIE SMEATON, Esq.,

Secretary,

Department of Revenue and Agriculture,

Rangoon.

FIRE BRICKS.

RANEENGUNGE FIRE BRICKS as supplied to Government and the various Railways, Iron Works, Coal, Gas, and Steam Navigation Companies. Price—Rs. 9 per 100.

Extract from Official Report of tests made at H. M.'s Mint, Calcutta, by THEODORE W. H. HUGHES, Esq., F.R.S., A.R.S.M., Officiating Deputy Superintendent, Geological Survey, India:—

"The Fire Bricks tested by me were furnished by the Firm of Messrs. BURN & Co. * * * The materials from which they are made are very refractory and capable of resisting high temperature without sensibly fusing. * * * That compared with Stourbridge Fire Bricks are somewhat superior."

The specimens were subjected to a temperature of over 3,000 degs. Fahr., the smelting point of Cast-iron being 2,786 degs. Fahr.

Apply for the above, and for Raneengunge Salt-glazed Stoneware and Imperishable Drainage Pipes, to

BURN & CO.,

7, Hastings-street, Calcutta,

or Raneengunge Pottery Works, Raneengunge,

E.I.R., Bengal.

FRANCE.**CONTINENTAL & COLONIAL AGENCY,**

ZULULAND AND CETEWAYO.

"I know what it is," he answered; "this honey is made from euphorbia flowers, which are very poisonous." This explanation made me feel exceedingly uncomfortable; but I elicited from him that there was not much danger, as the 'maass' taken with it would neutralise the effect of the poison. Directly he mentioned poison I dived into the packs, and pulled out a bottle of ENO'S FRUIT SALT, and emptying a quantity into two pannikins, filled them up with water, and several times repeating the dose, in a few hours we were considerably better."—*"Zululand and Cetewayo," (p. 139), by Captain W. R. Ludlow, 1st Batt. R. V. Royal Warwickshire Regiment.*

"What on earth shall I take to Zululand?" asked my friend Jim Law one day at Aldershot, when he had just received orders for South Africa, to start at forty-eight hours' notice. I replied, 'If you take my advice—and it's that of an old traveller—you'll not budge without a few bottles of ENO, even if you leave half your kit behind. I never am without these Salts, and, please the pigs, never intend to be.' On his return I inquired, 'Well, how about ENO'S FRUIT SALT?' 'My dear fellow, it was the best advice you ever gave; they saved me many an illness; and when I left Tugela, I sold the remaining bottle for ten times the original price!'—*Lieut. Col.*

JEOPARDY OF LIFE. THE GREAT DANGER OF DELAY.

You can change the trickling stream, but not the raging torrent.

WHAT EVERYBODY SHOULD READ.—How important it is to every individual to have at hand some simple, effective, and palatable remedy, such as ENO'S FRUIT SALT, to check disease at the outset! For this is the time. With very little trouble you can change the course of the trickling mountain stream, but not the rolling river. It will defy all your tiny efforts. I feel I cannot sufficiently impress this important information upon all Householders, or Ship Captains, or Europeans generally, who are visiting or residing in any hot or foreign climate. Whenever a change is contemplated, likely to disturb the condition of health, let ENO'S FRUIT SALT be your companion: for, under any circumstances, its use is beneficial and never can do harm. When you feel out of sorts, yet unable to say why, frequently without any warning you are suddenly seized with lassitude, disinclination for bodily or mental exertion, loss of appetite, sickness, pain in the forehead, dull aching of back and limbs, coldness of the surface, and often shivering, &c., &c.; then your whole body is out of order, the spirit of danger has been kindled, but you do not know where it may end—it is a real necessity to have a simple remedy at hand that will answer the very best end, with a positive assurance of doing good in every case and in no case any harm. The pilot can so steer and direct as to bring the ship into safety, but he cannot quell the raging storm. The common idea when not feeling well is, "I will wait and see, perhaps I shall be better to-morrow;" whereas, had a supply of ENO'S FRUIT SALT been at hand, and use made of it at the onset, all calamitous results might have been avoided. What dashes to the earth so many hopes, breaks so many sweet alliances, blasts so many auspicious enterprises, as untimely death?

ENO'S FRUIT SALT.—"After suffering for nearly two and a half years from severe headache and disordered stomach, and after trying almost everything and spending much money without finding any benefit, I was recommended by a friend to try ENO'S FRUIT SALT, and before I had finished one bottle I found it doing me a great deal of good, and now I am restored to my usual health; and others I know that have tried it have not enjoyed such good health for years.—Yours most truly, ROBT. HUMPHREYS, Post Office, Barnstaple."

SUCCESS IN LIFE.—"A new invention is brought before the public, and commands success. A score of abominable imitations are immediately introduced by the unscrupulous who, in copying the original closely enough to deceive the public, and yet not so exactly as to infringe upon legal rights, exercise an ingenuity that, employed in an original channel, could not fail to secure reputation and profit."—ADAMS.

CAUTION.—Legal rights are protected in every civilized country. Examine each Bottle, and see the capsule is marked "ENO'S FRUIT SALT." Without it you have been imposed on by worthless imitations. Sold by all Chemists, price 2s. 9d. and 4s. 6d.

DIRECTIONS IN SIXTEEN LANGUAGES HOW TO PREVENT DISEASE.

Prepared only at ENO'S FRUIT SALT WORKS, HATCHEM, LONDON, S.E., by J. C. ENO'S Patent.

SUTTON'S SEEDS.

TESTIMONIAL.

From S. Jennings, Esq., late Vice-President of the Agri-Horti. Society of India.

"With reference to your mode of packing seeds for export, I must say how much I was gratified with the system you were so good as to show me. During the whole of my long Indian experience, it was my constant regret that English packed seeds were almost invariably lower in germinating power than the American. After seeing the elaborate precautions you take in executing such orders as that of the Agri-Horti Society of India, I am by no means surprised to hear that you have been gratified by the receipt of so much testimony from the tropics as to the condition of your Seeds upon arrival."

OVER 450,000 FEET SOLD DURING 1881.

- Including 3,877 feet of main Driving Belts, of widths ranging from 13 in. to 60 in., are working in over 6,000 Mills and Works in Europe and America.

Proving Tests (by Kirkaldy, of London) show the relative strength and value, compared with Leather.

| | Breaking Strain per Square inch of Section. | Price per foot. |
|--|---|-----------------|
| Best Double Leather 8 in. Belting | 3,572 lbs. | 5s. 7d. |
| Gandy's 6 in. x 8-ply Cotton | 6,811 lbs. | 2s. 6d. |

THE GANDY BELT.

Any Length or Width
for Main Driving.

It is the best belt ever made for all purposes. Much Cheaper and Stronger than Leather. Thoroughly Waterproof, and not affected by temperature, clings well to the pulleys, runs true, and can be made any length without joints.

This Series of Belting (see engraving) was supplied in One Order to Messrs. John Crossley and Sons, Halifax, May 1, 1880, and continues to give entire satisfaction.

THE "GANDY" BELT.

GANDY'S Patent American Cotton Belting can claim a superiority over leather belts in every particular; its cost being about half that of leather, while its strength and gripping power is about double that of the best leather, as shown by repeated tests taken by Kirkaldy, of London. These tests are given above, to which special attention is directed. These "Gandy" belts are made of any width up to 72 inches, and any length up to 840 feet without joint, thus obviating the necessity of having two belts on the same pulley, a system of driving which is never satisfactory, as it is impossible to have belts of exactly the same tension; hence, one or the other is always causing a stoppage. These stoppages are avoided by using Gandy's Patent Belts in one width. These Gandy Belts are made of the finest American Cotton Duck, specially prepared at Baltimore for the purpose, and then put together and finished by Gandy's patented special Machinery and process to prevent stretching, and render them impervious to atmospheric influence. Possessed of advantages such as these, the universal adoption of Gandy's Belts can only be a question of time.

A SUBSTANTIAL GUARANTEE GIVEN WITH EVERY MAIN DRIVING BELT.

CORRESPONDENCE.

TASAR (SILKWORM) CULTIVATION.

(To the Editor of the Ceylon Observer.)

SIR,—In Major Coussemaker's Report on his experiments in 1881, there are one or two points which call for the attention of all interested in the cultivation of the wild silk-producers. The experimental clearing established at Poona (the expenses of which are defrayed by the Indian Government) consists of a plantation of *Lagerstræmia Indica*. The plants are grown at the distance of one foot apart in the rows, seven feet between each row, and the shrubs are kept topped at the height of four feet. All branches are removed with the pruning-knife as fast as they are bare of leaf by the worms, and in this way a constant supply of succulent foliage is produced.

Major Coussemaker states that in the Ahmednager Collectorate the natives habitually cut back their trees very hard, two-thirds of the trees being pollarded each year, and that this system of cultivation is "most favourable to the Tasar worm, for the constant lopping of the trees and burning of the branches and leaves harass the squirrels, birds, lizards, and wasps, while the fresh shoots which spring from the mutilated trees afford the best food possible for the worms." There can be no doubt that the natural foes of the worms are in this way put to a great deal of inconvenience, and that the constant attention rendered necessary by the process of regularly pruning the shrubs, which Major Coussemaker recommends, makes the destruction of lizards and other enemies a rather easy matter, but I cannot concur in the opinion expressed as regards the suitability of the tender foliage as food for the worms.

In the cultivation of the mulberry-feeding worm *Bombyx* neglect to supply mature leaf has largely tended to increase the debility which either too great kindness, or too little care, has engendered; and it seems reasonable to suppose that the wild worms, which in their natural state never devour the young leaves unless driven to do so by a scarcity of food, should become speedily debilitated when fed on immature leaf. In attempts made to rear the *Atlas*, *Militia* and other larvae indoors on branches, the stems of which are plunged in water, it is invariably found that the foliage becomes, sooner or later, distasteful to the worms, and although the strongest of them may escape disease and spin good cocoons, the majority are more or less affected by the excessive moisture in the leaf. The same deterioration is produced by severe or frequent pruning.

Major Coussemaker attributes his want of complete success to the existence of some climatic influence that he was unable to contend with, or to the worms having been attacked by small spiders, mosquitoes, or other minute enemies. It is quite possible that many of the worms were killed by insects, but detection in cases of this kind should not be difficult, and I think it almost certain that it was the want of properly matured leaf that caused his losses, since he himself admits that some of the worms commenced spinning before they were full-grown.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parentheses, or in a foot-note. The bighah in particular varies so much in the different provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

All correspondence must bear the full name and address of the writer, not necessarily for publication, but as a guarantee of good faith. We shall take no notice of anonymous letters.

MADRAS GOVERNMENT SCHOOL OF AGRICULTURE.

CANDIDATES for admission into the new class, about to be formed, are informed, that the revised rules and regulations will be published in the *Fort St. George Gazette* of Tuesday next, the 21st August 1883.

(Sd.)

W. R. ROBERTSON, M.R.A.C.,

Agricultural Reporter to Government,
in charge of the School of Agriculture.SAIDAPET;
17th August 1883.

The reason why so many are unable to take Cocoa, is, that the varieties commonly sold are mixed with starch, under the plea of rendering them soluble, while really making them thick, heavy, and indigestible. This may be easily detected, for if Cocoa thickens in the mouth, it proves the addition of starch. Cadbury's Cocoa is genuine; it is therefore three times the strength of these Cocos, and a refreshing beverage like tea or coffee.

The most wholesome and nutritious of confections is far less consumed than it would be were it not for the greatly adulterated articles sold under the name of chocolate. Every cake of chocolate bearing the name of Cadbury is guaranteed to consist solely of pure Cocoa and white sugar. Makers to the Queen.

M. Wally, in one of his reports on silk-producing worms reared in London, mentions an instance in which a number of *Selene* and *Luna* larvae which were fed upon a nut tree, that had been tapped and heavily pruned, died one after another, although other worms from the same brood of eggs reared on other trees growing close by, but unpruned, spun very fine cocoons.

It is of the utmost importance that the cocoons produced, whether of Tasar or other wild species, should be as free as possible of the cement which the worm naturally secretes. Mr. Thomas Wardle, in his recently published handbook of "The Wild Silks of India," states that Major Coussmaker has succeeded in obtaining perfectly white silk by causing the Tasar worm to void all its cement before allowing it to spin its cocoon, but particulars of the method are not given. Inasmuch as the quality and quantity of the cement in the wild cocoons depends largely on the health of the worm, it would seem that in the production of Tasar silk by Major Coussmaker's method a decrease in the amount of the cement must be accompanied by corresponding loss of vitality in the worm. And this is a very serious consideration, because it raises a barrier in the way of progress towards the domestication of the insect, for it would, of course, be useless to attempt to utilize for breeding purposes cocoons, spun by worms whose constitutions had been impaired in this way. Any naturalist, I suppose, who has studied this subject, will admit that the silkworm, when it is prevented, by any cause, from commencing to spin its cocoon at the appointed time, is more or less injured by the delay; and there is also a considerable loss of silk to be taken into account. It is only by rearing one brood after another, and by feeding each successive generation on the same kind of plant that any real progress can be made. The moths of this species do not readily pair in confinement, at first, and it would add considerably to the cost of production if the sericulturist were compelled to rely on any of the wild insects he might procure in the jungles for renewing his stock.

It is in another direction that we must look to effect an improvement—from the manufacturer's point of view—in Tasar silk. What is required is that the food-plant should be of such a nature that the worms reared on it would secrete as little as possible of the cement, which at present so greatly depreciates the value of the cocoon; the plant should also be one on which the worms are easily reared. If these conditions are fulfilled, one of the greatest difficulties in the way of Tasar cultivation will have been removed. There are probably many indigenous trees which might be utilized with this object, but prolonged experiments will be necessary to enable us to ascertain the most suitable, and in this investigation the chemical analysis of various kinds of foliage might be of great service. In judging of the effect of the food on the silk, it is important to bear in mind that temperature and other surrounding circumstances exert some influence on the colour and texture, and it is not safe to infer from the appearance, size, and weight of a few individual cocoons that the food-plant on which they were produced is beneficial or otherwise. The Tasar worm is extremely polyphagous, as much, perhaps, in the Ceylon hills as in the low-country; and it is impossible for worms proceeding from such a parent stock to produce cocoons of uniform character until they have been reared through several generations on one species of food-plant. In a former letter on this subject, I mentioned, I think, that the Tasar worm was found in the hill country feeding on the loquat and the Avocado pear trees. I have not had sufficient time to ascertain whether either of these would be of use in the direction indicated, but experiments might easily be made with them. The sapu is another tree from which good results might be expected, but as I have not yet heard of a single instance of the Tasar being found in a wild state on this tree in Ceylon, it is probable that a good deal of patience should be required in inducing the worm to adopt it. Whatever trees are selected, it is essential that they should be perfectly healthy: no foliage that has been 'forced' by heavy pruning, by manuring, or by irrigation, can be good food for the worms, and trees that are shaded or deprived in any way of their proper quantity of sunlight are equally objectionable.

I have mentioned the sapu as being probably one of the trees best suited to our purpose. In "Silk in India," compiled by Mr. J. Geoghegan, I find the following note on the silk of *Antheraea Assama* (a closely allied species, if not a variety merely of *A. papia*):—"Champa: the silk produced from the worm feeding on this plant (*Michelia*) gives the finest and whitest silk." There is another tree which may probably be made use of since it is commonly met with in the jungle over 4,000 feet elevation. It is the tree the leaf of which so closely resembles the tea leaf that coolies are hardly able to distinguish them. It is probably

Eurya serrata. The Atlas worm feeds on this tree in India, and there should be no difficulty in getting the Tasar worm to feed on it also.

In Dimbula worms of *Atlas*, *Selene* and *Mylitta* have been reared on the Avocado pear and on loquat, and in their wild state these three species may be found on the so-called "patana oak," the *kakata*.

There are other species of wild silk-producers, the cultivation of which might have given even better results than the Tasar, but the acclimatization of these is matter of time, and the commercial value of their silks has yet to be ascertained.—Yours faithfully,

PERCY N. BRAINE.

The Indian Agriculturist.

CALCUTTA, SEPTEMBER 1, 1883.

AGRICULTURAL BANKS.

THE question of Agricultural Banks is at present occupying a considerable amount of attention. Generally stated, some such opinions as the following are gaining daily in strength the banker namely that is devouring the cultivator by usurious interest, and if Government were to take the place of the banker, it would be satisfied with less interest. As a contribution to the literature of the subject, we present our readers with the following article, written by one who is in hourly contact with and who lives among agriculturists. The article therefore embodies the opinions of a man who knows the people well:—

The prime cause of the great need for bankers, among land-owners and cultivators—poverty and indebtedness—is seen by all to have its foundation in increase of population, not followed by sufficient emigration.

The peace and protection to life and property afforded under British rule have obviously tended to greatly increase the population. The natives of India receive the advantages of civilization, but refuse to throw aside ancient usages, &c., failing from want of knowledge to realize how unsuited they are to the present rule, how, though once perhaps essential to the proper working of an obsolete administration, they are now only anomalies, and as such must eventually die out.

The practice from the continuance of which we confidently believe most serious consequences are to be apprehended, is the one by which a man's estate is divided equally among all his children.

There was a time when lawlessness was the rule in India rather than the exception, as it now is, when a man's wealth was protected, and represented by the united physical strength of his family; and we can imagine how a father—in fact, a whole family—would grieve over the departure of a stalwart younger son capable of using a sword or wielding a *lathi*. In those times every inducement would be offered him not to leave the family, and none more reasonable than an equal share in his father's property. Uncultivated land was to be had in plenty then, near home, and as a family increased in numbers, the area of land required for its support could easily be increased. Population, however, increases indefinitely, but the area of a country is limited. Because of the increased area under the plough, the value of land has increased. We can point to a village in the Agra district which was sold about 60 years ago by public auction for Rs. 800, and is now well worth, at 3 per cent profit, to the purchaser Rs. 1,25,000.

The youngest son of five of a zemindar—the owner, "one *bhains*," 1/20th share, perhaps 20 acres of a small *zameen*—is brought up to consider himself a gentleman and a zemindar, and is hourly stuffed by his foolish relatives with all sorts of stupid ideas and tales about the extravagances that denote the *amir*, or gentleman. After his father's death he is put in possession of his property—a pair of lame oxen and four acres of land. The career of this man need scarcely be

We will now endeavour to explain who the banker or sowkar is. Happy is the cultivator who can furnish his own *rabi* seed ! There is no more certain evidence of incipient prosperity, and why ? Because he has had the whole year before him to trade with it. Well aware that profit in trade is largest where most labour and pains are taken, he lends it out on interest, in small quantities, to his less fortunate neighbours, recovering it before his own sowings commence. He is now a banker, a small sowkar, dealing only with grain, and repeating to himself the proverb, "*An dhan onek dhan : sona chandi adha dhan*" grain wealth is great wealth : gold and silver is but half wealth) meaning of course that you will not lose by it. In seasons of scarcity as soon as his capital has increased sufficiently, he elects a few regular customers, calls them his *assamis*, and treats them in a manner that will be described hereafter. It is, without exception, the aim and ambition of every cultivator to be a banker, as he acquires wealth most surely by these means. His reason for this, as most other native reasons from facts difficult of comprehension, are puerile quibbles and superstitious notions. This is what one of them told us : — "What can you expect from *matti mata* (mother earth) but what a child expects from its mother, viz., food ? Confine yourself to cultivation alone, and the good and bad seasons will, ~~and~~ balance themselves as to leave you a bare subsistence because the surplus money is *manjhus* cursed, or if this is not the correct translation, uncanny. Do not we say *dhori aur jhori*, the earth and a daughter, meaning thereby that the profit acquired from both, in the case of the daughter, by her sale, are as accursed as each other ? You must combine trade with cultivation if you wish to be wealthy, for it has the effect of taking the spell off the profit from cultivation alone."

Then the cultivator in a much worse position than the zemindari banker. He is undoubtedly the worst of the three. This sounds inconsistent, and will require lengthy explanation. The speculative banker settles in a village with the permission of the zemindars, and according to the extent of his capital takes up the maintenance of ryots. The most ancient description of the trade was apparently giving the grain to the applicant at one seer above the market price ruling on that date, and receiving it back at the harvest rate. What we call the harvest price is spoken of by natives as *aktij ka bhow*—the *aktij* rate; *ti* means third, and the prefix *ak*, or rather *aksh* meaning death, is added to define the particular 3rd day of the 2nd half of the Hindi month of *Baisakh* (between 23rd April and 23rd May 1883), as it is one of the two days of the year on which offerings of oblations to the souls of departed relations is an imperative duty on Hindoos. This is also the date for which the harvest price is fixed. A few days after the *aktij* the cultivators, sowkars, zemindars who are interested in the welfare of their tenants, or their representatives, putwary and weigh-master, meet with the object of fixing the harvest price, which they do by taking the mean of the prices that ruled in the nearest large mart a couple of days before and a couple of days after the third of the second half of Baisakh. Both sides—the money-lenders and those that deal with them—argue the matter, giving instances of sales, &c., and when the price is settled to the satisfaction of all, the banker is paid back at one seer more per rupee than whatever rate has been fixed upon. Of course, grain is cheapest at this time of the year, and when prices fluctuated a great deal, we can readily see how this simple system would to bring a certain and good profit to the sowkar; but it is now not much resorted to, particularly in localities within easy reach of the railway, which we know to have the effect of equalizing the price of grain, keeping it pretty regular all the year round, which would of course lessen the interest, when this is only the excess of the harvest rate over the average rate of the years. However, it is now no longer quite set aside, as we will see when treating of the banker's account book. Our reason for believing it to be one of the oldest systems of banking, is that the wor

for trade in the most ancient Hindi now spoken is *tyarash*, obviously derived from *ti*, the third day of the month, and *arash* security, or the security of the third.

Many writers have expressed themselves of opinion that the fixing of the harvest price is entirely in the hands of the *buniya*, and is a great hardship on the cultivator. If this were so, the country would have been ruined long ago. We do not place any dishonesty beyond the *buniya*, but these gentlemen have evidently lost sight of the fact, that though *buniyas* as a caste are very apt to form leagues, this particular trade is, in agricultural tracts, carried on under the competition of every caste of natives in India, for reasons that we have given, and that it is very difficult, if not impossible, to form leagues under the circumstances. It is only in towns where there are no agricultural bankers, and the grain vendors are almost all *buniyas* by caste that tricks can be practised. Then, again, out in the district, where cultivators are continually appealing to you about wrongs done them, a complaint against the validity of the harvest price is never heard, when the *aktij* rate has been duly fixed in a large village, the neighbouring villages generally save themselves the trouble of a conference by accepting it. A favourite ailage with them is *bhao aur bursat* or prices and rain, meaning that they are as much dependent on chance as each other. In the same way a harvest price used to be fixed for the *kharif* harvest called *mirigair ka b'hor*, in the month of *Mirigair* or *Aghan* (between the 15th November and 15th December 1883), but it is now very unusual to establish it with any ceremony.

We are now to see how the banker deals with his *asamis*. He has advanced one of them, we will say, Rs. 100, to be paid from the *kharif* harvest carrying interest at 2 annas per rupee for 6 months, or Rs. 25 per cent per annum. The money has been advanced gradually, supposing that there is no security but that of the crop—*no* (afterwards to be spoken of as grain) perhaps for a plough bullock; *no* rice not being put into the cultivator's hands, but paid to the cattle-dealer either by the banker himself, or through a trusty servant, Rs. 40 for food given at intervals, and Rs. 40 for rent.

Before giving cash advance, the banker, seized with a fit of nervousness, will walk over his patron's cultivation to see that it is not being neglected in any way and will stop advances if it is. The *asami* is supposed to feed himself from about the 15th August to the 15th November from the Indian corn, *bajra*, *not*, vegetables, &c., that he has sown, and the banker does not demand these crops, unless he contemplates throwing over the cultivator, expecting himself only cotton, *juar*, *masina*, &c. After this, and up to the 15th March, he will feed him on barley, never allowing more than 2 maunds, 20 seers (ordinary weight) per month for a family of five; salt and condiments must be procured by exchange from this allowance.

Very much the same is done in the *rabi*, seed of course being a heavy charge here, though scarcely anything in the *kharif*, the cultivator has to supply himself with food from about the 15th March to the 15th June, and does so chiefly from such crops as potatoes, carrots, *methi*, spinach, and is allowed to pluck a little green wheat and barley or grain.

The banker takes over the whole crop, allowing only the debts of customs to be paid on the threshing-floor. The village barber, potter, carpenter, washerman, water-carrier, family priest, and *bigari chamar* (a gentleman we shall write about on some future occasion) who each get, what will on an average come to about 25 seers of grain per plough, and charges interest on every item paid by him, but for such portion of the rent, which is always last considered, as is covered by the value of the produce.

It is the due payment of the tenant's rent that makes the *zemindar* support the *soukar*. It is usual for the latter to give him *rukka* or informal note of hand in favour of the tenant, pledging himself to pay the rent when the cultivator's crop is reaped. This is really no binding document, in the ordinary sense of the word, as it is neither stamped nor witnessed. It is only a note from the banker, acknowledging the cultivator to be a solvent customer of his, and one he does not intend throwing up. So identical are the interests of banker and tenant, at a

certain period, that these *rukkas* are as safe as possible, and such a thing as their being dishonoured is almost unknown.

The *zemindar* has now the upper hand of the banker, for if he was to eject the tenant, it would be impossible for the latter to collect his balances. So long as the interest already realized by the banker will not cover the anticipated loss, and leave a margin of at least 12 per cent profit on investment, this state of affairs remains, and the cultivator is supported by a capitalist who is bound in his own interest to furnish him with advances when necessary, but as the ryot says, *kismet phutah, aur buniya chuta*; that is to say—the *buniya* deserts you with the appearance of misfortune. The time comes when his cattle die to a calf, added to which is perhaps the loss of a couple of able-bodied members of his family, or probably worse, and the crop does not represent the full rent, or perhaps just it. The *buniya* now informs the *zemindar* that the security for his money has decreased so much in connection with this cultivator, that he can only afford to give a *rukka* for two-thirds of the rent. The *zemindar* cannot object, for he is told that if he does, and distrains the crop, the *buniya* will throw over the tenant, and he shows that having made such a large interest, about 50 per cent, previously, he can afford to do it, and show a fair profit in spite of the money he loses by doing so. Now, the question is, will the *zemindar* come to terms with the banker, or will he distrain, and secure all his rent for that season? In the latter case, he would be burdened with not only one impoverished tenant, who would require advances to keep him going, but one deeply indebted to a merciless creditor, no longer interested in his welfare, who, with his fraudulent bonds and decrees, and executions, would neutralize all the good effects of the advances, and give a great deal of trouble generally.

In the majority of cases, the former course is preferred, and the *buniya* allowed to risk his money in another year's trial. This season most likely decides the fate of the cultivator between a long term of indebtedness and perfect boggary; another bad season, and the *buniya* throws him over, with, by reason of his purely mercantile training, as little compunction as he would discard a worn-out pair of shoes. Prayers are useless with this class of people, who would say what an English-speaking Bengali was heard to utter: "Money matter no friendship."

It would be a dead loss to a *zemindar*, or something very near it, to keep such a cultivator any longer in a thickly cultivated country, where land is at a premium. The man's ruin being chiefly due to the very high interest he has been obliged to pay, the land itself will generally bear enhancement, and it is accordingly made over to some solvent ryot on an enhanced rent, the enhancement being looked upon in the light of a recovery by instalments of the arrears of the ejected tenant.

The following figures will show the percentage of interest realized by a *soukar* from an *asami* he is supposed to have advanced Rs. 200 during the year. It will be seen that the old *aktij* system we have already described is so mixed up with the new one of two annas per rupee per harvest as to make it exceedingly doubtful whether the "country lout" can really understand the terms he has accepted, or the interest that he is paying:—

| Kharif. | | Rs. | As. | P. |
|---|-----|-----|-----|----|
| 1—Registered value of grain advanced at intervals at the rate prevailing on each occasion | ... | 100 | 0 | 0 |
| 2—Interest at 2 annas per rupee per <i>fasil</i> | ... | 12 | 8 | 0 |
| 3—Interest, the result of deducting 1 seer per rupee's worth of grain when making advances, taking the average price of grain at 20 seers per rupee | ... | 5 | 0 | 0 |
| Total | ... | 117 | 8 | 0 |
| Deduct item No. 3, already realized | ... | 5 | 0 | 0 |
| Balance due by tenant at end of <i>kharif</i> | ... | 112 | 8 | 0 |

This being a half-yearly account and the sum really paid by the banker Rs. 25, it looks like an innocent Rs. 36-13-5 per cent per annum. But when we reflect that this balance, if cleared, would be paid at harvest time when grain is at the very least 20 per cent cheaper than the average rate of the past six months, and that it would be paid at one seer above this rate or five per cent more, we find that the deluded ryot will have

really paid Rs. 28-4-0 more. That is, the soukar gets Rs. 45-12-0 within 6 months for Rs. 95 laid out, or 95-5-0 per cent per annum.

Let us suppose that he does not pay up in the kharif, and that the balance is carried over to the rabi. It would stand thus if he paid up at the aktij:—

Rabi account.

| | Rs. | As. | P. |
|---|-----|-----|----|
| 4—Balance of kharif | 112 | 8 | 0 |
| 5—Interest on kharif balance of Rs. 100, minus kharif interest at 2 annas per rupee per faal | 12 | 8 | 0 |
| 6—Compound interest on kharif interest of former account item No. 2 at 2 annas per rupee | 1 | 9 | 0 |
| 7—Interest of 5 per cent on items 4, 5, and 6, by receiving grain 1 seer above market price | 7 | 5 | 3 |
| 8—Recorded value of grain advanced at interval, at the rate prevailing on each occasion | 100 | 0 | 0 |
| 9—Interest at 2 annas per rupee per faal on item No. 8... .. | 12 | 8 | 0 |
| 10—Interest of 5 per cent while advancing grain (No. 8) 1 seer below market rate ... | 5 | 0 | 0 |
| 11—Interest of 5 per cent while receiving back grain (No. 8) 1 seer above market rate ... | 5 | 0 | 0 |
| 12—Compound interest of rupees 5 while receiving back (No. 9) at 1 seer above market rate | 0 | 10 | 0 |
| 13—Profit, the result of the difference between the average rates of the year and the harvest rate at which the debt is paid, on items 6, 4, 5, 8, and 10—20 per cent, about... | 42 | 0 | 0 |
| • Total | 305 | 0 | 3 |
| Plus rupees 5 received in the kharif | 5 | 0 | 0 |
| Total | 310 | 0 | 3 |
| Deduct actual sum paid... .. | 190 | 0 | 0 |
| • Profit | 120 | 0 | 3 |

This is about 63 per cent which bankers will acknowledge to, as being only right and proper. In the event of such an unusual circumstance as prices falling below the last harvest rate, the cultivator is forced to receive advances at the latter rate, being told that it is the identical grain he paid last harvest, and that he surely does not intend taking it back at a cheaper rate than he gave it.

This is the toss-hazard on the principle of "heads I win and tails you lose," in right earnest. Yet soukars complain that they are often ruined. We do not doubt it, and it is painful to think of, but the sadder reflection remains that their customers must have been utterly annihilated.

The question is, does the zemindar profit most by supplying advances himself? If he is a large landowner he cannot afford the time to attend to such a difficult business. Cultivators are too improvident, and too accustomed to the "feast-or-starve" principle of life, as a rule, to be entrusted with money in lumps. It must be given in small instalments, and the advancer must make sure that it is used for the purpose it is given for only; this is by no means an easy task, or one that can be entrusted to native servants; such tenants will grind and devour choice wheat given for seed; will sell oxen purchased for them; and several have been known to produce the same ox when told that they would not be entrusted with cash till they showed the animal they intended purchasing. Besides this, those requiring advances being chiefly impoverished and thriftless tenants, certain to be already in the zemindar's debt, there is not an atom of security for his money.

There may have been a time when the zemindar was the *malik* (father and mother), the chieftain of his village, with perhaps the life and death of his tenants in his hands; when he used to show magnanimity towards them, and pride himself on their being happy and prosperous. We have established a different condition of things; the zemindar is now no better in his own opinion than a common lessee, a servant collecting money for us, and money the regular payment of which we must enforce with the utmost rigour.

Setting aside the matter of occupancy rights, the lowest caste of cultivator stands on an equality with a zemindar of the highest caste in open court, and could be the means of getting him flogged, notwithstanding that the latter would not and could not touch him without contamination. This is the law of civilization, and we would not mention the matter were it not to show, that for a great while to come, we must expect no poetry from the average native zemindar, and having taken the chieftainship into our own hands and deprived the ryot of his *bap-mat*, must act the part ourselves.

The zemindar's interest in the cultivator is purely mercantile just now; no poetical sentiments regulate his conduct towards him, and we are afraid that in thickly populated tracts where land is at premium, it pays him better to eject an impoverished tenant than aid him with advances. If he is deeply involved with others, it is always his interest to eject him.

We will now find it easier to explain the position of the third or zemindari soukar whom we accused of being of the very worst class. We have seen that a banker deals with well-to-do tenants, giving them up when they are ruined, or rather, as is often the case, after he has ruined them, and left the inference that the model zemindar advances money to men already ruined with the object of re-instating them. This shows the difference between *takavi*, as agricultural advances are called, and *soukari* or banking. In the latter, the speculator, if careful, will never lose, but in the former he will often find that he is "throwing good money after bad." As long as the zemindar and banker are separate, both fear each other and restrict one another in extortion, and to a certain extent the ryot is a gainer, but where both occupations are carried on by the same individual, the ryot is an abject slave.

One would reasonably think that where the zemindar is also banker, it will never be to his interest to ruin a tenant; but a little reflection will make it apparent that it is rack-renting of the very worst sort. Cultivation in such villages is very indifferent, and the tenants always of the lowest castes, and even natives look upon it as very bad form. Every particle of grain first comes to his garners as it would to any other banker's. Between banking accounts such as we have shown, which is the simplest form, and land rent, there is seldom, if ever, a balance left to the credit of a tenant. So that this class of zemindars gets all the produce of his land for very, very much less than what it would have cost him had he cultivated himself, by hired labour, for which there is some competition. These cultivators are wheeled into the belief that they are ordinary tenants, and labour under this impression for a bare subsistence. The advantage to the zemindar does not end here; having all the produce in his own hands—for he would instantly eject any one that would not deal with him; he can afford to fix as low a rent as he pleases, and will give all his tenants, or more properly, slaves, occupancy rights before the settlement takes place, intending of course to make them resign, to a man, after the settlement is over, for, with the others, he hates occupancy rights. Is he not bound to be dealt as gently with by the settlement officer as possible? We can fancy the following dialogue:—

S.O.—"How very low your rents are, Puraram. Your liberality in the matter of occupancy rights does you great, great credit. I regret to say that very few have taken your example.

Z.—Ah, sir! it is the greatest mistake in the world to rack-rent your tenants. The Ganges bears me witness that I consider it a sin. My father's last injunction to me was not to oppress the ryots. "They are my children," were his words; and let the revenue be as high as it will, I cannot do it—death and ruin are preferable.

S.O.—But, Puraram, these settlement rates are not heavy.

Z.—Not for those who extract the last drop of blood from the poor, and those whose souls burn within them at the very mention of occupancy rights.

The interrogator, now confusing *takavi* advances and banking (two utterly different things, when the zemindar is concerned, as we have explained), probably says:—

I am told you have to lay out a good deal of money in *takavi*—strange, considering the lightness of your rents and the quality of the soil,

Z.—(Rising to go)—Sir, God is above and you are below ; such is my fate (*dashing his hand against his forehead*), but you see and hear everything, and it is not necessary for me to speak.

We fancy we can hear the shrieks of laughter that will rend the air from the *chhopal* of that canny thakoor that evening, and the sighs of his tenants.

Should Government organize agricultural banks, this thakoor will probably send all his tenants to secure Rs. 20 a piece at 2 per cent, or whatever it may be, would take it from them, and lend it out at 25 per cent, or start a grain trade with it—as sure as he is born. This class of banker should be suppressed speedily, and with a high hand. The first or agricultural banker deserves consideration. His competition is the greatest check we know of on the speculative banker, and his main business being the production of the grain, he cannot be forced out of the petty banking market, at all events, nearly every agriculturist that has an ounce of grain to spare deals with it in the way we have stated. It has the effect of distributing wealth to some extent and is antagonistic to hoarding. Were that to be suppressed by Government banks, more jewels would be hung about the necks of native wives and children, and more money buried in pots than is already done ; for the cultivator cannot trust himself with another trade. The love of trade grows on human beings and gets as irresistible as gambling, and though we care not for the latter we should do all in our power to promote the former. When by means of banking with brother cultivators and money-lending (the particulars of which we have not entered into, as it does not concern cultivators so much as labourers and artisans) he has accumulated about Rs. 500, not less, he starts as a grain merchant, purchasing grain in the district and disposing of it in large cities ; still retaining his banking work, but entrusting his cultivation to some competent and very near relation. Such a man is to the zemindar the pink of the present cultivators, for one who has acquired wealth by agriculture only is very rare. His cultivation is always of the best class, and even should he not be an occupancy tenant, his land has as much money expended on it as the anticipated profit will admit of. He knows full well that it will not pay the zemindar to eject him.

We wish to protect the cultivator, and tax this man daily for carrying on a banking business. This we certainly should not do when certain that he does not cultivate less than ten acres at least. It amounts to expressing ourselves satisfied if he sells his grain at once at a dead loss to a speculative grain merchant, and dissatisfied because he accepts all the risk and trouble of lending it to his less fortunate neighbours, and thereby securing a better price.

The soukar's interest is high ; 63 per cent is very high we are aware, and that it is necessary that something should be done to protect the men that requires his services. But all soukars charge the same, and the fact of their being much competition among them, is very significant, and would point to the conclusion that the security offered very often is nothing more than the crop, and that, liable to distraint by the prior right of a third party, is very poor and insufficient. Such a thing as a banker ruined by bad seasons is by no means unheard of. If the security was better, there is no question about it but that a smaller interest would be charged.

Government agricultural banks would in all likelihood prove a failure, on account of the difficulty of management. Besides the difficulty of determining who can and who cannot be trusted, everybody that knows the class of cultivators that will flock to these banks will tell you that they must be treated like children ; that it will never answer to put sums of money into their hands which they may keep at home, and spend gradually,—it being absolutely necessary to see that they do not mispend loans, but utilize them for the benefit of the crop, which is nine times out of ten the only security. They must be watched to see that, inspired perhaps with a feeling that the crop will not do more than cover their debt, and leave nothing over for them, they do not neglect

it. The banker at present, as we have remarked before, gives the instalments in small quantities of grain and threatens to stop advances the moment he observes the least neglect ; and he must be a good agriculturist to know what constitutes neglect—certain slight omissions and at particular periods often influencing the produce for the worse a great deal. Then, as the present law is constituted, it would be ruin to the zemindar if these banks in any way interfered with his right to collect his money before any other claimant, particularly such a powerful "limitationless" one as Government would be, or with his right of having the crop hypothecated to him. These are the only rights of any value left him, and their loss would cause a panic. It is also very questionable if the water-rate system would answer. There the advantage to both zemindar and tenant is indisputable, and the water cannot be mispent, so as to hurt either of them, whereas money given can. At present the numerous sowkars watch the interest of the zemindar unwillingly by enforcing proper attention to cultivation—a thing the large landholder (landowner would be a misnomer if applied to the zemindar) could never do without the assistance of a staff that could not be afforded, even if procurable. If, being the landowners, we are determined to aid the ryot, *why not stand surety for him*, doing so only when his banker is a brother cultivator ? We know that bad security necessitates the heavy interest charged, and that between servant and servant we can expect no other relation than that of trick. With such security as Government could offer, 25 per cent per annum would be remunerative to incipient bankers, and much less to wealthier.

Some conditions like the following could be arranged :—

Every banker entitled to accept Government security must be registered.

None to be registered if cultivators of less than 10 acres, unless occupancy tenants, or able to prove themselves hereditary agriculturists.

Such bankers will not be taxed (*and some other social privileges must be thought of.*)

Cultivators, on the recommendation of three or more solvent and respectable brother cultivators residing within 3 miles of their village, to be given two foils of a trefoil security note of a certain value (*after paying a small premium, which may go to form a fund for the benefit of ruined agriculturists*), which note they may make over to any registered banker they please to deal with, or that pleases to deal with them ; the banker retaining one foil, and returning the other signed to the office that issued the note, to be pasted against the office counterfoil.

The whole matter would of course require much consideration. Means would have to be devised to prevent the soukar charging more than a certain interest ; to prevent him paying away the money too rapidly ; to prevent him getting careless as to the attention bestowed by the cultivator on the crop ; to ensure his having rightly stated the amount he has paid, &c. Many of these could be managed by means of the surety note itself, by some such arrangement of tearing off slips as we have in the stock note. Conditions of the security would also have to be determined upon.

This would surely be more paternal, and contain less of the objectionable element of interference with free trade.

Perhaps if a premium of Rs. 1,000 was notified for the best essay on agricultural banking, in the Hindi language, and to be written in Hindi characters, facts would be arrived at that could not be elicited by any conference of Europeans, or wealthy native zemindars fishing for titles.

The non-agricultural banker should be properly held in check in his dealings with cultivators. They are almost always bunyas by caste, whose chief business is speculating in grain, and who only undertake the ruin—we cannot call it anything else—of cultivators. The high standard of integrity among them enables them to take advantage of the telegraph (a sealed letter to the ordinary cultivator), combined with freedom of motion, not being hampered, and confined to a locality by husbandry, gives them too great an advantage over the agriculturist already, and it is a question whether they should not be still further suppressed, by a simple device we know of, by which the most ignorant and illiterate cultivator

could be made aware of the daily prices of grains in, at least, the nearest large mart.

W. C.

FRUIT AND FLOWER WINES.

IT is well known that the demand for wines far exceeds what is produced from the grape, and that their fabrication has for years been openly carried on in France and England. A different state of things prevailed of old, for fermentation was a phenomenon not understood, and the composition of wine was unknown. The blending, therefore, of the old wine with the new, and the addition of water, were the only sophistications practised. Now, it is different. The advance of chemistry has revealed what was formerly concealed, and men have not been slow to take advantage of this knowledge. As a consequence, the glory of the vine may be said to have departed, because all the romance chronicled in song and story is inapplicable to the almost indistinguishable imitations flauntingly sold as *wine*. The fact, however, that wines are artificially made tends only to confirm the growing demand for them; and the question occurs—why should we, because the production of the grape is insufficient to meet this demand, disregard other fruits which ferment in a like manner, and whose products operate in the same way? If we seek to ascertain why most men are content with the base imitations offered to them, we discover that they do not know what genuine wine is—that a wine is to them excellent because it is high priced, and genuine because the cask in which it is received bears a French name or the bottles' chaste labels in white and gold. A would-be connoisseur solemnly tastes such a liquor, and utters an opinion, although he has never to his own knowledge tasted a genuine wine; but that is nothing: he is a *bon-vivant*. He pretends, therefore, to a knowledge of wines which takes a chemical expert years to acquire, and which he (the expert) does not hastily apply. To these self-constituted judges do we owe the existence in the market of many a spurious wine, and by such judges are really good wines condemned.

Partly on account of their cheapness, and partly through frivolous report, ordinary fruit wines have not hitherto met with much favour, and but scant attention has been given to their manufacture. Notwithstanding this, they are still in use—it may be said by old women, priests, and shepherds. Well; we should prefer to be guided by the simple tastes of such people than by the opinions of self-constituted connoisseurs whose tastes have become vitiated by indulgence in the abominable apologies for wine vended in cities.

The relationship between ordinary fruit wines and grape wines is obscure to a degree: some believe them to be preserved fruit juices, and others saccharine fluids, flavoured with artificial fruit essences. To establish the fact of their actual connection is a very simple matter. Chemistry having ascertained all the changes which take place in grape juice in its transformation to wine—that is, the metamorphosis of certain of its components, the consequent evolution of certain gases, change in colour, density, &c., it is easy to follow the changes which take place when other fruits are brought under the same conditions and influences, and to compare their products. This has been done, and we have arrived at the knowledge that all fruits containing sugar and gluten are subject to the same kind of fermentation: that they will yield products of more or less potency, which, keeping in view the literal signification of the term *wine*, have all claim to that name, all of them bearing a higher hygienic interpretation than most of the so-called wines found in the market, and certainly not an inferior hygienic interpretation to that based on the components of pure grape wine. It is from a technical point of view, however, that we will chiefly treat them in this notice.

Fruit wines in use in Russia are those prepared from the apple, bilberry, brambleberry, cloudberry, cranberry, currant, raspberry, strawberry, and whortleberry. In Great Britain we have in addition to these, wines prepared from the gooseberry, elderberry, cherry, juniper-berry, mulberry, the orange, lemon, fig, plum, pear, and other fruits. All of these wines possess in a very pronounced degree the characteristic *bouquet* of the

fruits mentioned, and probably the medicinal virtues in a modified degree of the plants yielding them. They are mostly acid to the taste, and on this account very grateful to the palates of persons suffering from fever. This acidity can be removed, if desired, by the addition of glucose, preferably in the shape of honey, to the fruit juice prior to fermentation. Care must however be taken that an excess of glucose is not added, else the characteristic *bouquet* of the fruit will be masked. The blend, however, of the fruit *bouquet*, with that of the mead, is when carefully made very agreeable, resembling that of grape wine. The addition of elder-berries or elder-flowers to this blend, or to fruit juices whose fermentation products have no very pronounced odour, lends to such the flavour of Frontignac. The addition of glucose, for the purpose of modifying the acidity, results of course in the formation of more alcohol, a circumstance taken advantage of by wine fabricators, and to which we owe the existence of a superior class of artificial wines; superior in so far that they are harmless, but whose connection with the grape is like the imitations of a worse type, shadowy. They are in fact nothing more or less than fortified gooseberry and currant, with a dash of questionable sauterne. We allude to certain brands of champagne and burgundy, so called; *chateau* something or another with the year of the vintage given. It is something however to know that they are harmless, for in France where the ravages of phylloxera have forced manufacturers to extremities, the beet is employed as a substitute for the grape. Beet-root wine is a pale red liquid, possessing a disagreeable taste and odour, and containing varying quantiles of propyl, butyl, and amyl alcohols. The latter is the well known fousel oil. It will therefore be understood that wines into whose composition fermented beet juice enters must be strongly excitant. We can understand the use of potato spirit in the manufacture of artificial cognac, but we can discern nothing of the proverbial elegance of French taste in the adoption of the beet as a substitute for the grape in the manufacture of wines. The very association of the two must be repulsive to most minds. We have then artificial wines, and artificial wines, some harmless and some poisonous, for that which gradually paralyses the brain cannot be regarded in any other light than that of a poison: the difficulty is to know the harmless imitation from the toxic. This being the case, and as no special measures are adopted by Government for the detection and suppression of the trade in such imitations, the question of utilising harmless-fruits, analogous in nature to the grape, for the manufacture of light refreshing wines, especially in India, becomes of importance. Tropical fruit wines would, we venture to predict, find a ready market in England. The apparatus necessary for their manufacture consists of a few tubes, filters and presses; the industry therefore need not be confined to capitalists. Considering the excellence of some of the Russian and British fruit wines, it is a matter of surprise that they are not met with in commerce under their own names. In alcoholic value they are not inferior to certain kinds of burgundy, hock, champagne, frontignac and tokay, as evidenced by their utilization for the manufacture of imitations of these wines. Perry, as perry, is too cheap to be appreciated: as champagne it commands a ready market. The name of *gooseberry* is against the product of that fruit; not being sufficiently euphonious to suit the pseudo-aesthetic tastes of the average Briton. As *grandarian* it might be a success. Should low prices be against these wines, they might be improved up to any standard—dry, sweet, still, and effervescing, and priced according to age. They differ generally from grape wine, in so far that they contain less alcohol, and less extractive. Following are analyses of samples of cloudberry and cranberry wine, in which the alcohol is very low. The amount of sugar indicated points to the cause of this, *viz.*, defective fermentation:—

| | | | Cloudberry. | Cranberry. |
|------------------|-----|-----|-------------|------------|
| Specific gravity | ... | ... | 1.04 | 1.03 |
| Extract | ... | ... | 1.12 p.c. | 1.04 p.c. |
| Ash | ... | ... | .13 | .15 |
| Alcohol | ... | ... | 1.15 | .80 |
| Sugar | ... | ... | 6.15 | 5.10 |
| Acid | ... | ... | .80 | 1.20 |
| Tannin | ... | ... | — | traces. |

Samples of currant wine have been found to contain over 80 p.c. of alcohol, by measure; gooseberry and orange nearly 12 p. c., elder 9 p. c., cyder 10 p. c., and perry nearly 8 p. c. With the exception of currant, these amounts are scarcely sufficient to keep them, but the standard may be increased, as already pointed out, by the addition of glucose.

Turning to India, the wonder is that we are not familiar with pine wine, tipari, and mango wine, and a host of others. Tipari fruit yields almost its own weight of juice, which on fermentation results in a delicious amber-coloured wine containing over 7 p. c. alcohol.

The amounts of sugar contained in the various fruits mentioned in this notice indicate the probable alcoholic value of their products. The apple and the pear contain of grape-sugar 6.7 p. c., increasing if the fruit is allowed to ripen. The orange contains 5 p. c., bilberry nearly 6 p. c., strawberry 4.5 to 7.5 p. c., mulberry and blackberry 9 p. c., raspberry 3.5 to 5 p. c. nearly, gooseberries and currants 7 p. c., plum 3.5 to 6 p. c., cherries 10 to 13 p. c., juniper berries 30 p. c., figs 48, dates 57, and the grape about 12 per cent. The more sugar the fruit contains, the richer will their wines be in alcohol. Some varieties of the plantain contain nearly 6 per cent inverted, and 16 per cent crystallisable sugar, the former increasing day by day at the expense of the latter, as the fruit passes from a state of sound to sleepy ripeness. This latter fruit is therefore not only well adapted for the manufacture of wine, or pure spirit, but for the manufacture of sugar, and could be used with advantage for increasing the alcoholic power of wines from fruits containing little sugar. The date and the fig, it will be seen, contain nearly half their weight of sugar; their value in wine manufacture will therefore be obvious. We are in want of exact information regarding the constituents of the mango, but we do not doubt that it contains a large quantity of sugar, and that a wine prepared from it would find much favour among the natives, who look upon the fruit as incomparable. The litchi and rose-apple would also we think repay experiment.

The amount of sugar contained in the nectar of many flowers warrants the presumption that a little perseverance would place us in possession of a series of wines or liqueurs of a very luscious nature. Fuchsia and red clover give nearly 8 milligrams of sugar per flower, nearly 6 of which in the red clover is grape-sugar, and as we ascend the scale to flowers having fleshy petals, there is a proportionate increase. An important feature in flower wines would be their medicinal value. Cowslip wine and poppy-flower wine are pleasant soporifics; and orange flowers are said to possess certain sedative and hypnotic virtues, the water prepared from them being used in the south of France to counteract the sleeplessness that tea is apt to cause with nervous persons. The honeysuckle we know to be anti-asthmatic. It therefore is not unreasonable to infer from the very pronounced medicinal characteristics of known flower wines, that all flowers capable of furnishing such, will possess the characteristic features of the plants yielding them. We may therefore look forward to the time when all remedies will come direct from nature's own laboratory in the form of fragrant and agreeable wines. How does this idea, we wonder, suit homoeopathy?

The flower of the mahwah tree (India) contains much sugar, and yields, besides a pleasant wine, a very intoxicating spirit; the latter, according to Major Drury, resembling, if carefully distilled, good Irish whiskey. The flowers are said to be exported from Bombay to France. A full-grown tree yields about 20 cwt. The central bud of the agave, an acclimatised plant, introduced by the Portuguese into India, yields a sour liquid which readily ferments, furnishing a strong alcoholic liquor. The plant possesses certain well defined curative properties, which, if possessed to any extent by the flower, would render agave wine an article of much value. A Tamil poet of times gone bye sung in praise of the palmyra, a plant applied for eighty-eight purposes. The flowering spathe of this plant yield a saccharine juice (palmyra toddy), from which an intoxicating liquor is made, and largely used by the common people. Wine and sugar are also made from the sap of the trunk. The flowers of many other palms,

notably the cocoa palm, are replete with sugar, and yield on fermentation excellent wines, and by distillation the spirit called arrack. Arrack is looked upon by many people as a very crude spirit. We submit that, were it subjected to the same elaborate distillative treatment as whiskey, it would vie with that fluid in purity. From the foregoing, it will be seen that the subject of the fermentation of fruits and flowers is, by reason of its being allied to things we know, easy of pursuit, and that pursuit of it might result in the foundation of a new and profitable industry.

It is likewise self-evident that the inauguration of such an industry will, next to the introduction of pure grape wines from hitherto undeveloped sources, do more than anything else to drive from commerce those high priced and elegantly got-up shams so frequently met with: which, instead of *exhilarating* as pure wine invariably does, gives birth to feelings quite foreign to many whose bad fortune it is to have such administered to them, or foisted upon them; and which, when frequently indulged in, sap the vigour of youth, render old men idiotic, women feeble, the uneducated rebellious, and the rebellious murderous. Here in the East, where there is much in all conscience to enervate, depress, and render life miserable it does seem hard that life's luxuries, those stimulants on which life often depends during sickness, should be sold without restriction of any kind; that palpably bad stock, seventy-five per cent of which are doubtless unreal, should be passed into commerce through H. M. Customs.

AGRICULTURE IN INDIA.

THE success of Baboo Ambica Charan Sen, M.A., Mr. T. Ozonne, the Director of the new Agricultural Department in Bombay, and of Syud Sakhawut Hossein, B.A., in obtaining the three first places at the Royal Agricultural College of Cirencester is suggestive. The Cirencester scholarships created by Sir Ashley Eden in 1880 will, in time, supply Bengal with a number of young men educated in the highest scientific school of agriculture in England. At home it is generally found that such men cannot earn a living as farmers, and there is little reason to expect better results in India, a country to which the principles taught in English schools have not been applied by direct experiments, and where land is cultivated in small holdings. They will, therefore, seek Government service, and no doubt will be employed, first as the managers of Government estates and of experimental farms, then as heads or members of agricultural departments in the different provinces. The Bengal Government is now commencing such management in one district, and there can be small question as to the tendency of the administration in that direction.

That Government may do a good deal for agriculture in this country is proved by the introduction of tea cultivation, which was the result of a State experiment, and the naturalisation of the cinchona plant, which now supplies, from Government estates, such a valuable febrifuge. On the other hand, all the Government studs proved failures, including that for mules at Darjeeling, in which there has never been a foal, and the model farms opened by Sir George Campbell had to be closed. The farm at Arrah caused a loss of ten thousand rupees in two years on thirty acres, cultivating ordinary country produce, or about the total value of the land is free-simple each year. The building was afterwards given for a *dames'* school, while the land of a similar farm at Arrah were assigned to a billiard-club. For managing a farm, Government agency is deficient in two respects, either of which would be fatal. In the first place, the management is conducted on *doctrinaire* principles, which experience shows never pay, until so thoroughly adapted to the circumstances that they cease to be *doctrinaire*. In the second place, there is not the same incentive to gain which a private farmer has, the farmer's anxiety to buy cheap and sell dear, to get workmen at the lowest wages, and exact the severest tasks from them and

DON'T DIE IN THE HOUSE.

"Rough on Rats" clears out rats, mice, beetles, roaches, bed-bugs, flies, ants, insects, moles, chipmunks, gophers. As. 6, p. 1. B. S. Mason & Co., Bombay, General Agents.

to make petty savings in every direction. In thrift, in empiest skill, and in exacting labour, Government must always be inferior to the ordinary farmer. On the other hand, it can try experiments which no private person would undertake, because the cost would fall on him, and the benefit go to others.

We hope that in future some considerable portion of the attention of Government will be directed rather to the model management of estates, than to model farms, and to the latter mainly in connexion with, and as a means to, the former. Government is in every district of Bengal-landlord, large tracts of land being its own property while it has to manage considerable estates for others. The position is one which it actually occupies, and the only question is as to how it will fulfil its duties.

On the other hand, Government is not at present a farmer, and need not be, unless it wishes. It is now pretty generally acknowledged that the past management of Government estates has been exceedingly bad. No improvements worthy of the name have been executed, the tenants have received neither aid nor direction, and the assessment of rent has been made according to the custom of the private zemindars of the district, and has therefore been excessive wherever these were extortionate. To keep the cheapest establishment for rent-collecting purposes, to keep no establishment for any other purpose, to get in the whole of the rent, and from time to time to raise the rent, have been the sole objects of Government. There is now, we are glad to observe, a change, though as yet it has borne little fruit, and we hope that the Cirencester scholars may be made the agents of future reform. They may be appointed to look after the larger Government estates, and set an example to private land-owners of what good management can do. Their knowledge of scientific agriculture would enable them to give the best advice to the ryots, which the special knowledge of the latter would enable them to apply. Among the improvements which they might effect we may mention draining, the storage of water against droughts, the introduction of improved plough-oxen by utilising better bulls, the improvement of the breed of ponies by getting better stallions, the planting of fuel reserves, the preservation of pasture commons from the encroachments of the plough, the procuring of better seed, the spreading of knowledge of the method of raising the more valuable crops, the supply of such approved agricultural instruments as of the Bebece mills, the protection of ryots from the extortion of money-lenders and the purchasers of produce, where such is needed, the encouragement of combinations for all useful purposes, the erection of primary schools, the making of roads, and the reformation of village conservancy. If trained Government officials set an example of such work on the Crown lands, the zemindars would be glad to imitate. At present Government preaches in favour of a zealous performance of the duties of a landlord, because every native zemindar can see how Government performs them.

A home farm ordinarily is a part of a system of good management of an estate, and it would be as useful in India, as elsewhere. But to be really a model, it must resemble the ryots' holdings in size. When Sir George Campbell made an attempt in this direction, Mr. Hume declared that a Government farm, to be a success, must extend over at least a thousand acres. Now we hope that nothing of this kind will be attempted. If it were successful, it would show zemindars how ryots might be evicted wholesale at a profit, and the income of one man improved by the ruin of thousands. Government might just as wisely establish a model school for house-breaking, with specimens of the newest Bill Sykes' tools and weapons. A thousand acres of land for a model farm can be obtained in Bengal only by evicting two hundred families, most of which may starve, and this is a price not to be paid for an experiment, which would, after all, be only for the advantage of those willing to imitate the crime of wholesale eviction. In small quantities land can be got on Government estates, and experiments tried suitable to the system of *petite culture* which prevails in the country. But it should be understood that such experiments form but a part, and a small part, of the general system of model management, to introduce which should be the object of an Agricultural Department.

EDITORIAL NOTES.

A CORRESPONDENT of the *Rural New Yorker* says:—"The whole poultry business, as managed by dealers in fancy poultry, is a delusion and a snare to any one who enters the business with the expectation of making a legitimate income from it. In their case the value of a fowl is not determined by the eggs or pounds of poultry produced, but the bird is 'scaled' by the size and shape of comb, color of feathers, style of tail, and similar nonsensical points. Let the farmer try a similar method in determining the value of the cows he buys, and how long will he be able to make dairying pay? Why is it not just as wise to purchase a cow for the color of her nose, the style of her horns, the color of her hair and the make-up of her tail, as to pay a fancy or absurd price for similar qualities in a hen."

In an interesting paper read before the Society of Arts, on "English Goods and Chinese Buyers," by Lieutenant the Hon. H.N. Shore, R.N., the following passage occurs:—"But the article of foreign commerce which threatens to distance all other competitors in point of popularity is kerosene oil. The development of the trade in this article has been remarkable of late. It is entirely supplanting the native bean and tea-oil, which has done duty hitherto for lighting purposes, and may be truly described as supplying a want long felt, Chinese social economy being sadly deficient in good house lights. The cheapness and brilliancy of the oil in burning makes it a great favourite. It has found its way to the most distant parts of the empire; nearly all shops are lit by it, and for hundreds of miles round many of the ports opened to foreign trade, almost every cottage will be found with its small tin lamp of native make for burning the oil. Its cheapness has had a somewhat undesirable result in Shanghai, so far as shareholders in the gas company are concerned, having prevented gas from coming into general use amongst the natives, who, it is stated, prefer to buy their oil in small quantities as they want it, instead of running up gas bills without any satisfactory check on household expenditure.

The oil is at present almost entirely supplied from the factories at Philadelphia, and the trade is practically a monopoly. From the high popularity it enjoys, there is every reason to suppose that, until the petroleum wells which are known to exist in China are opened up, the importation of the foreign article will continue to increase for many years to come. The extent of this increase may be gathered from the following returns:—at Hankow, the imports rose from 27,976 gallons in 1877, to 285,157 gallons in 1880; at Wu-hu, from 2,190 gallons to 71,110 gallons during the same period; while the returns for Shanghai show that, in 1879, the importation reached the prodigious total of 4,780,440 gallons.

THE *Boston Commercial Bulletin* prophesies that a large source of wealth for the Southern States is in their timber. In New England, the timber supply, it says, is already exhausted; so of the hard woods in Indiana and Ohio, while the pine forests in Wisconsin and Michigan are being rapidly denuded. In this dilemma the lumbermen are turning longing eyes upon the southern woodlands.

THE *American Chemical Review*, in its latest issue, gives the following description of the use of sulphite of magnesium as a defecating agent in sugar works:—"This invention substantially consists in operating the defecation by means of basic sulphite of magnesium, which is used either alone or previous to any addition to the liquor of caustic lime or other strong bases apt to decompose organic matter; and the object of the invention is to produce in the liquor alkaline sulphites and insoluble magnesium salts and to coagulate albuminous substances, while the formation of soluble calcic salts and of caustic alkalies is avoided as much as possible. At the same time the liquor is decolorized to a great extent.

The process may be carried out in different manners. One method of proceeding is as follows:—Sulphite or bisulphite of

magnesium and caustic magnesia are mixed together in water in such proportions, that the compound thereby formed will show basic reaction, and of this compound a sufficient quantity is added to the liquor at a temperature adapted to the quality of liquor and to the quantity of foreign matter contained therein. The said sulphite or bisulphite of magnesium and caustic magnesia may be such as form articles of commerce. Instead, however, of combining these substances as described, sulphurous acid may be introduced either in liquid or in gaseous state into caustic magnesia, stirred up in water, so much acid being added as is necessary to impart to the solution the required basic character. With this process hyposulphurous acid and trithionic acid may be formed; but this is of no consequence. In case too much acid should have been used, caustic magnesia is subsequently added in the proper quantity.

The second mode of proceeding consists in producing the basic sulphite of magnesium in the saccharine solution, by separately adding to the same the requisite quantity of caustic magnesia and sulphuric acid, or sulphite or bisulphite of magnesium. Instead of caustic magnesia, a magnesium salt, which is decomposed by sulphurous acid, may in either case be employed. The defecating medium having been well mixed with the liquor, which at the time of mixing may be warm or cold, the latter is heated or maintained in the heated state until the solid matter has separated out and the liquor has become clear. In case a complete separation should not yet ensue, so much more caustic magnesia is added as is required to produce the desired effect.

It will generally be found advantageous to subject the liquor, after it has been filtered off from the sediment produced, to a subsequent treatment by lime, baryta, or strontia, or by the hydrates or the saccharates or the aluminates thereof, for the purpose of decomposing such of the sulphites formed as are acted upon by the said substances, and of precipitating any magnesia which may have been dissolved.

In case any of the substances named should have been added in excess, such excess may be neutralized wholly or partly by means of carbonic or sulphurous acid, or of both combined, or by the use of any other known and suitable precipitating medium.

From the sediment produced by the defecating process, the magnesium sulphite and the caustic magnesia may be recovered by means of known chemical processes. Moreover, the ammonia and other nitrogenous compounds contained in the sediment may be extracted therefrom either in the same process or by a separate treatment.

The inventor is aware of the fact that acid sulphite of magnesia has been proposed as a defecating agent, but the use of basic sulphite, as devised in his patent (U.S. Pat. 268,987), he claims, is new and different in its action. The claims made in connection with this patent are as follow:—

The method of defecating saccharine liquors, which consists in adding to or forming in the liquor basic sulphite of magnesium, and, if required, in subsequently adding caustic magnesia, the process being carried out previous to the aforesaid treatment of the liquor by lime or other strong bases, substantially as and for the purpose described.

In combination with the method of defecating saccharine liquors by means of basic sulphite of magnesium and caustic magnesia, as described, the subsequent treatment of the liquor by lime, baryta, or strontia, or the hydrates, the saccharates, or the aluminates thereof, substantially as herein specified.

In combination with the method of defecating saccharine liquors, as hereinbefore claimed, the employment of carbonic acid, or sulphurous acid, or any other known and suitable precipitating medium, for the purpose of partly or entirely precipitating any bases added in excess.

Belgium, says a correspondent, is the most carefully and elaborately-cultivated country in Europe, and the Belgian farmers raise larger crops per acre in their small, unfenced, and finely-lined farms than are raised anywhere else. Farming there partakes of the nature of gardening; indeed, it would be called gardening elsewhere. Wheat is the important crop, and the

management of it is particular to what other people would call an extreme. The seed is sown in the fall—spread broadcast and thick over rich and well-prepared plant-beds, similar to those which Missouri tobacco-raisers prepare for their tobacco seed. The young wheat comes up thick, rank and strong in the fall, and remains so all winter, forming a mat on the ground. In the spring the ground is thoroughly prepared by deep ploughing and harrowing, after which it is marked off in drills ten inches to one foot apart, one way. The wheat plants are then pulled up from the bed in bunches and carefully picked apart, one at a time, and dropped at distances of four to six inches in the drills in the field. After the dropper follows the planter, who, with a trowel or thin paddle, makes holes in the drills at the proper distances, and sets out the separate plants in the same manner as strawberry, tomato, or tobacco plants are set out. When the work is done there is a wheat field planted in drills one foot apart, and with the plants six inches apart in the drills. It is a tedious and particular process. But on the small five-acre Belgian farms, worth \$200 to \$500 an acre, it amply pays for the trouble. The Belgian wheat fields, after being planted, are carefully cultivated between the rows by hand until the plants are too high to admit of further work. The plants branch into stools from each of which shoots up stalks bearing heavy heads of grain; and when the harvest comes, the yield is 100 to 150 bushels of grain to the acre.

A CORRESPONDENT writes:—The diminishing supply of good foreign tobacco has forced the French Government to consider the question of its home cultivation. For three years experiments in the south-western portions of the country have been carried on; the results have exceeded the most sanguine hopes. Last year despite the cold, wet season, the yield of tobacco was so satisfactory, that an important area of land is at present devoted to tobacco, soils of a sandy character being preferred, such being the kind on which the best brands of Havana are raised. Climate does not seem to be the decisive factor in tobacco culture. In the West Indies, tobacco is cultivated during the winter season, that which signifies a temperature equal to the summer heat at Bordeaux.

The culture of tobacco can replace the destroyed vineyards, and another consolation has been found in the cultivation of China grass or ramie. The great obstacle, up to the present against the latter, has been the want of a machine to bark or skutch the stems, and set the fibre free, cleanly. Such is claimed at last to be found, as a company has been organized not only to construct the machines, but to hire them out to the farmers: further, the company in question guarantees to supply seed and plants at reduced rates, and to take all the grass raised.

The following is from the *Colonies and India*:—Within the last twenty years a vast extension of the economic uses to which this valuable fibre [cocoa-nut fibre] is put has taken place. The term "coir," usually applied to this material, is the Anglicised form of the South Indian "kayaru," cord or twine, and is not applied in India to the raw fibre, which is called in the Tamil language "savuri." The fibrous husk or rind of the cocoa-nut is easily stripped from the nut while yet green, by striking it on the point of an iron spike, and then is steeped in salt or brackish water, where it lies for several months, until the softer portions of the husk rot away, and the strong fibre alone remains. This is taken out, beaten with a stick to separate and clean the fibre, and twisted with the required number of strands into rope, or woven into matting, while the stiffer fibres are made into brushes and other articles of domestic utility. The fibre is pressed for shipping into bales, weighing 200 lbs. each. The attempt has been made to prepare the fibre from the dried husk in England, but without success.

Much of the coir fibre used in England is brought from Ceylon; but a large and increasing quantity is now exported from Bombay and the Western Coast of India. The supply is not inexhaustible; but as prices rise, cultivation is encouraged, and as the growth of this palm is along the sea coast, where other crops cannot be grown, the trade is a profitable one.

Factories for the weaving of coir matting have been opened by English and American firms at Alleppy, Quilon, Colachel,

Cochin, &c., and turn out a considerable quantity of goods. Spinning is not attempted here, being more cheaply done by hand at the places where the fibre is produced. Along the coasts of the backwaters and canals, many people may now be busily engaged in scraping and cleaning the fibre and twisting it into yarn. In the factories the yarn is first sorted to its various shades and qualities. The warp is made by boys running backwards and forwards; then it is flattened and smoothed for weaving by being run through heavy rollers. The weaving is tedious work, performed by men, who earn two or three rupees a week at it. The web is again rolled to give it some finish, wound securely in a roll, and marked.

Large profits have been made in this manufacture in India. But it can now be carried on so much better in England, with the machinery and appliances available here, that large quantities of the yarn are exported. One firm in Lancashire have introduced steam loom weaving of this material. The various shades of fibre—cream-coloured, reddish brown, and blackish—which vary greatly according to care and skill in preparation, are first carefully separated, and cocoa-nut matting is now made of fine quality with pretty shades of colour and in pleasing patterns, so as to be available for higher uses than the very coarse makes, and the material is most durable. The yarn is also plaited by machinery into cinnel or belting.

Cables made of coir bear exposure to salt-water better than anything else, the tannin which it contains preventing the fibre from rotting; they are exceedingly light and buoyant, as well as elastic. Coir cordage, in Dr. Wright's experiments, broke at 224 lbs. weight. Even the refuse and broken fibre can be turned to account for stuffing mattresses, and is used in horticulture, &c., as no insect will touch it.

The exports from Travancore of this material form a large proportion of the trade of the district, and amounted, in 1879-80, to nearly 150,000 cwt., valued at 13½ lacs of rupees (say £137,290), and paying to the Government a duty of 68,000 rupees. Of the cocoa-nuts themselves, nearly 9,000,000, valued at nearly 2,60,900 rupees, and paying customs duty 13,000 rupees, were sent away. Other products of this palm exported as oil and copra or dried kernel, were valued, the former at 3,22,100 rupees, and the latter at no less than 26½ lacs of rupees, making a total value of the export of products of the cocoa-nut palm, from Travancore alone, of 46½ lacs of rupees (nearly half-a-million sterling). Some thousands of tons are also exported from Cochin.

Cocoa-nut fibre is so durable, useful, and economical a material that a great future is assured for the industry; and, as prices rise, the natives will pay increasing attention to the collection of the whole amount produced, and to its careful preparation. Perhaps, when, through increasing demand, the fibre becomes still more expensive, it may be found possible to prepare it of greatly improved quality and appearance by steaming or boiling so as to avoid the pollution of ponds and backwaters by the decomposing pulp of the husk, and the consequent blackening of the fibre so often observed. The textile ingenuity of the present age of invention may perhaps devise some additional uses for this fibre; hats and bonnets made of this material have, it is said, attracted much attention.

A CORRESPONDENT of the *North British Agriculturist* has the following note on the application of nitrate of soda:—Regarding the most economical use of 'nitrate of soda,' I find that much depends on the nature of the soil to which the manure is to be applied. A clay soil or a soil containing upwards of 50 per cent of clay is capable of retaining fertilizing matter that may be applied to it until the crop is able to make use of it. In such a case nitrate of soda could be safely applied under either condition. Such does not apply, however, to light soils or such as contain only a small percentage of clay; these soils are, generally speaking, minus a class of bodies known in chemistry as 'silicic acid,' or at least do not contain them to any great extent. These 'double silicates' are composed of the 'silicate of alumina,' part of the 'alumina' being displaced by an equivalent of soda, lime, potash, ammonia, as the case may be. It is these bodies, then, that give to a soil power to hold fertilizing matter for the use of crops.

On light soils where there is a possibility of these bodies not being present in the required strength, nitrate of soda or any other rapidly soluble manure should never be applied, till there was active vegetation to make use of it as it is dissolved, and in such a case it would be nonsense to talk of sowing nitrate of soda on a wet day or during wet weather, for thereby it would dissolve rapidly in the rain, with it be carried down through the soil to the drain pipe, and be lost.

It is not precisely known, says a contemporary, from what period the cultivation of hemp in Anjou dates, but it is recorded that in 1748, the Joubert family established, by royal permission, a sail-cloth factory at Beaufort-on-Vallée, which was afterwards transferred to Angers, where it still exists. In 1753, the brothers Danton obtained the privilege of founding at Angers the manufacture of printed goods, but this industry seems to have failed to establish itself permanently in the district. There are (according to the *Moniteur des Filles et Tissus*) several important houses at Angers engaged in the hemp industry, whose products are favourably known in other countries.

Within the last thirty years wages have considerably increased in the Angers district, the augmentation being about 25 to 30 per cent for spinners and other operatives engaged in the earlier stages of manufacture, while weavers are receiving double the wages they were getting in 1850. The introduction of power-looms has increased the quantity produced, thus allowing of an augmented remuneration to the workpeople engaged in this branch of manufacture. The general condition of the operatives is far more comfortable than was formerly the case. This result is due in a great measure to the spread of economical habits amongst the working population. In one factory every workman, who saves 100 francs during a year out of his wages, receives from the firm 15 francs as interest. This harmony of feeling between employer and employed allows of industrial changes being carried out when necessary, without the difficulties arising which are often met with where a less friendly tone prevails.

A GERMAN chemist, Herr Maximilian Ziegler, has just patented, it seems, a new process for manufacturing a substitute for gutta serena. About 56 kilos of powdered copal and 7½ to 15 kilos of sublimed sulphur are mixed with about double the quantity of oil of turpentine, or with 55 to 60 litres of petroleum, and heated in a boiler provided with a stirring apparatus to a temperature of 122 degs. to 150 degs. C., and stirred until completely dissolved. The mass is then allowed to cool to 38 degs. C., and is then mixed with about three kilos of casein in weak ammonia water, to which a little alcohol and wood spirit has been added. The mass is then heated to the former temperature (122 degs. to 150 degs. C.) until it is a thin fluid. It is then boiled with a 15 to 25 per cent solution of nutgall or catechu, to which about half a kilo of ammonia has been added. After boiling for several hours the mass is cooled off, washed in cold water, kneaded in hot water, then rolled out and dried. It is claimed that the resultant product is much cheaper and cannot be detected from the real article. It is said to wear equally as well.

HOSHIAHPORE is one of the largest sugar-producing districts in the province. The cane is there grown almost entirely on *barani* or unirrigated land, and to many a village is a source of great prosperity and wealth. It is a wonderful sight to see in January or February the great plain of the land, about 10 or 12 miles south of Hoshiahpore on the way to Jullundur, covered with 100 ploughs busily working to prepare the soil for the reception of the (so-called) seed.

The process of manufacturing is as follows:—

The juice, *ras*, is boiled till it is thick; when being boiled, it is cleared with the mucilage of the bark of one of two hill trees *pulu kydia calycina* or *bahal* (*grevia*?). The mucilage, when prepared for use, is called *suglai*; after the juice has been thickened by boiling, it is called *rab*. Out of the *rab* is pressed the molasses or *shira*, being strained through a bag made of coarse blanket. *Shira* is worth at Hoshiahpore nearly Rs. 2 per cwt. After the pressing operation is over the

remaining mass, red in colour, is laid in large wicker troughs called *khanna*, and covered with a thick layer of water weed, *shala*. There are two species used, *bhatu* and *kareli*. They are, I believe, species of *Tallinnaria* (*Apiralia* ?) or *Potamogeton*, but I have not succeeded in identifying them. As the layer of weed ferments, the sugar turns white, when it is taken off. A fresh layer of the weed is put on during three days for some weeks (in Sirmoor from commencement of *Chet* to end of *Baisakh*). Sometimes the sugar-cane crop is much injured by frost, and this is of course a great calamity to the district. I recollected one year, 1880, great damage was thus done. In Gharmaur (Pergunnah Garhahankar) the people sold their cane for seed at about Rs. 140 per acre of standing cane. This they found at that time more profitable than to press it, for the juice would not have brought in more than Rs. 60 to 90 per acre.

If the soil is too dry, the frost is said to be hurtful to sugar-cane: the soil of the Serwal tracts in the south of the Hoshiarpore District is said to be good for cane on account of the moisture it contains which enables the cane to stand the frost.

In Hoshiarpore the varieties are—

Dhauhu.

Chann.

Kanara.

Ekar.

Dhauhu and *Chann* are the varieties most commonly cultivated in the Serwal, I believe. *Dhauhu* is said to be the richest in juice, and if a certain quantity of juice has been contracted for, *Dhauhu* would be the kind cultivated to meet the contract.

Chann, however, is a better cane, giving more sugar. So if the produce is for home use *chann* is preferred to *dhaulu*.

Ekar is the variety most cultivated in the hills. It is said to be hard and harsh-tasted, and wild pigs do not attack it when full grown: a great advantage to the hill tracts.

Kanara is cultivated here and there, mixed up with other kinds. It is very soft and suitable for chewing.

In appearance the four kinds may be distinguished as follows:—

Dhauhu, light green stem.

Ekar also light green, but has black longitudinal lines or splits in each joint or *pori*.

Chann is thicker, with brown or purple patches of bloom on the lower joints.

Kanara is thin with short joints, very sweet, and soft like silk.

A CORRESPONDENT of a contemporary has the following on the coffee grub:—

With grub, as with leaf-disease, only some drastic application for their utter extirpation once and for ever was considered worthy of a fair trial. Similarly as with the fungus, I contend that we have unwittingly fostered the insect by a system of applying manure which obtained some ten years since, and also by the nature of the fertilizers themselves. The soil on being slackened up immediately round the stem of the tree was scraped away by hand, in order that as few roots as possible might be disturbed, and cocoanut poonac and castor cake were spread in the hollow thus made and covered up with earth, thereby forming a soft mound into which the beetle, with no difficulty, burrowed for the depositing of its eggs. Here were all the conditions essential to grub life. The soil was undisturbed by coolies working amongst the coffee; incubation went on apace; sufficient sunlight reaching the spot through the centre of the tree, which is always kept handled out. The grubs, on reaching that stage, found they were indeed in a bed of roses: turn where they would cocoanut and castor cake were in abundance; not only that, but a mass of tender rootlets were ready for their operations. Small chance of a single egg or larva perishing here, and little wonder that the tree rapidly shed its leaves; but a short space of time was necessary to deprive it of every feeding rootlet. Ever since there was a coffee estate there has been grub, but not to the extent we have it now, and if we are to reduce their numbers we shall only succeed by rendering their conditions of existence hard. This can be accomplished by applications of fertilizers obnoxious to the insect, dug broadcast into the soil. In spreading the

manure over a larger area, we not only induce a larger root surface, but we reduce the chances of every rootlet being reached and make grub life harder.

From constant communication with the Entomologist for the Royal Agricultural Society of England, and through experiments carefully conducted here, I have come to the conclusion that rape cake, in which mustard seed forms a considerable proportion, is a remedy as well as a valuable manure, for I have found it is the only substance of the kind that they cannot exist on; Castor and cocoanut cake they seem thoroughly to enjoy.

Miss Ormerod found that forty-eight hours' confinement in rape cake kept moist was sufficient to kill wire-worm outright. This ought to be encouragement to those who are continually looking for specifics to give rape cake a fair trial. In case of disappointment, however, I should advise those who purpose experimenting to be careful that they procure the cake I mention, as I understand pure rape is shipped from many parts of India, into the composition of which no mustard seed enters. Manures in the manufacture of which sulphuric acid is used, such as dissolved bones and superphosphate of lime, are also very offensive to grub.

The only antidote with which I am acquainted and which at the same time is innocuous to the roots of plants, is powdered mustard, but my experiments with it scarcely warrant me in stating that the quantity used, to be effective, would be practicable, owing to its cost. Later on, I shall be glad to communicate the result of my experience.

I may mention that on my attention being directed to the use of mustard seed by hop farmers in some parts of England, as a remedy for wire-worm, I procured a few bushels, which have had the most satisfactory results in expelling the insect from the soil on which it was sown broadcast, and mulched in green before it reproduced seed.—DIOGENES.

A CORRESPONDENT of the *Madras Mail* writes:—

The financial results of the manufacture of poudrette by the Municipality of Adoni, which you noticed in your issue of the 7th instant, is not well calculated to induce more Municipalities to adopt that system of disposing of the night soil. The manufacture of poudrette has successfully solved the much-contested question of removing the night soil and street sweepings in a manner thoroughly efficient, and their subsequent utilisation as a manure. I would that a voice were raised, feeble as it may be, in favour of its manufacture, in a more extended form, by other Municipalities in Southern India. Its advantage, over other modes of disposing of excrementitious matter, may be considered under the heads of sanitation and economy. The practice of many of the Municipalities as regards the night-soil is to cart it to some place beyond the limits of the town, and there deposit it in deep pits excavated for the purpose, or what is worse to spread it out over existing swampy hollows. Here decomposition sets in, worms and maggots are generated, and the nuisance caused by a stuff that is naturally foul is aggravated a thousandfold; and it continues in this state of putrefaction for months together. But the process of manufacturing poudrette does not occupy more than five days, and even in the rainy season it hardly exceeds ten days. The material manufactured is as harmless and inoffensive as dry earth. It is also the most economical way of removing the night-soil. The deodoriser used in its manufacture so completely and within a few minutes covers up the noxious smell and removes its injurious effects, that neither the eye nor the nose can perceive anything offensive. For this reason it may not be necessary to have the poudrette depot very far removed from human habitations. But when night-soil is wastefully thrown away in deep pits to putrefy there, contaminate the surrounding air, and endanger health, it is indispensably essential that the depot should be as far from the town as possible. Now, in the manufacture of poudrette, the heaviest item of expenditure is cartage of the night-soil, which amounts to about three-fourths of the total cost. The actual process of converting this stuff into poudrette costing a mere iota. Thus the cartage for the extra distance entails heavy expenditure, and runs up to more than the

cost of manufacturing poudrette, which is the cheapest method of disposing of the night-soil, immaterial of any profit, that might accrue from its sale. The advantages of poudrette do not stop here. They are elastic, and must expand in course of time. When the merits of this material come to be duly acknowledged, and when the deeply-cherished prejudices of the native cultivators have worn away, the financial results will present quite a different aspect. A few facts will be more effective than a whole string of arguments, and it would be better to cite a few. The report on the working of the Poona Municipal Poudrette Depot, and its financial results, for the year 1882, are as startling as they are satisfactory. It is interesting to note how reluctant the agriculturists were to use poudrette at the outset, and how its worth, as a manure, gradually rose in their estimation before the happy results of the year under review were achieved. The amount realised by the sale of poudrette in 1875 was Rs. 766, while the cost of manufacture was about Rs. 18,000. In seven years the demand for this stuff rose so much, and the competitions at the sales became so keen that in 1882 the proceeds from the sale poudrette rose to Rs. 30,776, while the cost was only Rs. 19,684, showing a net profit of Rs. 11,092. The report says: "Seven years ago agriculturists would not touch poudrette thus prepared, and could not be induced to take it away even at a nominal charge. At present the out-turn of the manure is not enough to keep pace with the demand. Poudrette is now sought for from a distance of twelve miles, and in one case it was taken to a distance of twenty-four miles for an orange plantation." Cannot the local Municipality be induced to make an experiment with poudrette even on the smallest scale? The collection and removal of the night-soil to the various depôts set apart for it, costs our Municipality two lakhs of rupees annually. This is about one-fourth of the total Municipal revenue. The quantity of night-soil collected in this city may be estimated at 30,000 tons a year. This, added to the deodorising material used, will yield 60,000 tons of poudrette. Taking Rs. 5 per ton as a very low price of poudrette, the revenue derived from its sale will be three lakhs of rupees. The expenditure will be only a trifle in addition to the two lakhs which the Municipality spends annually. It is very gratifying to reflect that the revenue of our Municipality can be enhanced by three lakhs of rupees annually, within a period of six or seven years, and that, too, without any extra burden on the rate-payers of this poor city, who are already groaning under a not overmuch taxation. This may look like a dream too beautiful to be realised, but have we not the experience of Municipalities like that of Poona, pointing to the feasibility of earning a not revenue from a system which in bygone years cost an enormous outlay without any profit?

Another correspondent says:—

I read with much interest the admirable communication in your paper of the 11th instant, touching poudrette as a manure. I agree with all your correspondent advocates, and I think there cannot be two opinions of the superiority of disposing of our night-soil by manufacturing it into poudrette over the old, and what should now be the obsolete custom of carting it away and burying it in pits. But your correspondent goes on to say, if I mistake not, 'it is the most economical way of disposing of the night soil.' Is that so? Has that been satisfactorily worked out? Because, if so, I do not see why all Municipalities should not convert night-soil into poudrette; for undoubtedly it is a cleaner and more efficacious way. If he means only, it is a more economical way if the poudrette can be sold, I am afraid he is leaning on a broken reed. The people of Southern India are intensely prejudiced on this head. I know of no place where the people will use poudrette. At Bellary you may see, a little way out of the town, a magnificent mound of this invaluable fructifier, but not a farmer can be induced to try it, although the municipality have offered, I believe, to give a large quantity away for nothing, if ryots will only remove it. In fact the use of poudrette is, I take it, one of the most important problems we have to work out. If, as in Poona, cultivators could only be induced to use it, most Municipalities would reap an income which would materially lessen taxation, but

Ramsawmy obstinately refuses, and what is to be done? Government might, perhaps, do something, though it is not very evident what. The most curious thing is, that cultivators have no objection to seeing their fields near towns and villages used as places of resort by the community, and I presume must recognise that their fields thus used are benefitted, but they obstinately refuse to have recourse to the more cleanly and efficacious means modern science places at their disposal. We must wait patiently for some enlightened man to arise and instruct his fellow-countrymen. Mr. Sabapathy Iyer, at Bellary, is doing his best, and is at present the Mochi of his day.

The Mexican Government has concluded a contract with Mr. Oscar A. Droege to plant two millions of trees in the valley of Mexico within four years, commencing March 15, 1884. Half-a-million trees a year are to be planted in such places as the Government shall decide. The contractor pledges himself to establish a number of nurseries, and to have in them each year at least 800,000 ash, 35,000 willows, 120,000 poplars, 60,000 eucalyptus trees, 60,000 troncos Japones, 60,000 mountain cypress cedars, 60,000 acacias, and 120,000 of miscellaneous varieties. The trees must be in plantations of from 50,000 to 100,000 each, and Mr. Droege has to maintain them for two years after planting. He is not compelled to plant trees along the highways, however. Three graduates of the School of Agriculture are to be received into the nurseries each year, there to study the science of forestry. He is also to raise fruit and other useful plants for free distribution. There is to be translated from the German every year a work on arboriculture of recognised merit. An inspector is to superintend, and Mr. Droege is to receive annually 40,000 dols. till the sum reaches a total of 200,000 dols.

EXPERIMENTS WITH LOCUSTS' EGGS.—Some interesting experiments on locusts' eggs have lately come to our notice. One dismal fact has been discovered, viz., that hatching and development will go on under what would ordinarily be considered most unfavourable circumstances. The egg, of a reddish brown colour, is about the size of a grain of wheat, but not quite so thick. A handful put into a tumbler mixed with earth and drenched several times a day with water continued to burst and send forth the young insect. A similar quantity mixed with dry earth in a finger glass and covered with green grass did likewise, with the only difference that those subjected to the periodical shower-bath were slower in hatching. Two or three eggs put into half a tumbler of water sank, but on the egg bursting to let out the young one it floated to the surface. This is certainly perseverance worthy a better cause—and must dispel the illusion that heavy rain would kill the locusts. It is curious to watch the convulsive struggles of the insect to free itself from the encumbrance of the shell. First appears the head, a moment's repose, and the whole insect bursts forth, lies perfectly inert for about a minute, and then a tiny green locust, unmistakable from the peculiar formation of the head, complete, except that he is wingless, hops about as frisky as the proverbial frolicsome kid. Mr. Bor's theory for their destruction seems to consist in the interception by means of screens four feet high on young locusts in the crawling stage. It would be interesting to know at what period of their existence they crawl. The writer has seen them five minutes old hop a foot. Efforts are being made in various collectorates for the collection and destruction of eggs. Many district officers, instead of enjoying at head-quarters the repose they have earned after eight months of the travelling season, are out in the districts after what is facetiously termed "locust shikar." Notwithstanding these most praiseworthy efforts, it is feared that unless nature steps in, much damage will be done to the young crops before they can be harvested.—*Bombay Catholic Examiner.*

The *Central Blatt für Textil Industrie* states that the superstitious views of the Buddhists had, until recently, prevented the extension of silkworm culture in Ceylon. According to the latest accounts, however, this opposition has been overcome, and silk is occupying much attention in several districts. The numerous insects and reptiles of the island have been found to render progress difficult; but it is expected that, by the adoption of such precautionary measures as are usual in

tropical countries, the new enterprise will finally be successful.

NEW YORK INDUSTRIES.—According to the census returns of 1880, there were at that time in New York 378,159 men and 135,218 women, making together 513,377 persons, including servants of both sexes, who obtained their living by the work of their hands. The various branches of industry amounted to 218, giving employment to 146,179 men, 71,795 women, and 9,878 children under 16 years of age. The capital engaged in these trades was £36,200,000, the wages amounting to £19,400,000, and the raw material to £57,680,000. These 218 industries were carried on in 11,339 establishments, including 839 boot and shoe factories, 782 bakers' shops, 761 tobacco manufactories, 736 clothing works, 460 carpenters' shops, 412 printing offices, 401 plumbers' shops, 229 furniture warehouses, 223 painters' shops, 177 tin-ware factories, and 174 saddlers' shops. A capital of £14,000,000 is sunk in the manufacture of waterproof clothing, and £8,010,000 in the boot and shoe trade, which provides employment for 15,000 persons in 120 establishments. No less than 30,000 tons of raw india-rubber are imported annually into the United States. Combined with other substances, it produces a total weight of manufactured articles amounting to 300,000 tons. The cost of raw india-rubber four years ago was under 2s. a lb., but it has now risen to about 5s. In consequence of this great rise in the price of india-rubber, attempts are made to replace it by other substances, such as celluloid.

INSTITUTE OF AGRICULTURE.—The Council of this Institute, which has been founded for the purpose of advancing technical instruction upon various sections of agricultural practice, have issued their second annual report, from which it appears that the total number of persons to whom certificates of merit have been awarded, during the present session, is one hundred and three. The arrangements for the next session consist of a course of 280 lectures upon agricultural science, from October 1st to May 3rd, 1884; a course of 60 lectures on poultry, dairy, and bee management, from March 10th to May 3rd, 1884; a course of ten Monday evening lectures on agricultural science from February 18th to April 28th, 1884. Research committees have been established, and are carrying on their respective inquiries upon root crops, farm seeds, and plant growth. The address of the Institute is South Kensington, S.W.

CHINESE TEA TRADE.—The returns of the export of tea from China and Japan during the past season continue to show a great decline in the shipments to this country. In the twelve months ending the 31st May, the total consignments to us were in round numbers:—

| | lbs. |
|--------|-------------|
| 1882-3 | 170,000,000 |
| 1881-2 | 164,000,000 |
| 1880-1 | 175,000,000 |

To the Continent the shipments were—9,360,000 lbs. in 1882-3, as compared with 10,100,000 lbs. in 1881-2, and 7,200,000 lbs. in 1880-1. Accompanying this decline in the supplies of tea which Europe has obtained from China, there has been a large increase in the supplies from India, and the Indian product would thus appear to be gradually ousting that of China from our markets.

The number of cattle killed in the Madras Presidency by wild animals was, it seems, 9,703, against 8,938 in the preceding year. Nearly three-fourths of the number fell victims to tigers and panthers. The loss was particularly heavy in Cuddapah and South Canara. It was also large in Vizagapatam, Golavari, Kurnool, Salem, Madura, Tinnevely, and Malabar. At the very moderate rate of Rs. 20 a-head, the 9,703 cattle destroyed by wild beasts represent a loss to the cultivator of about 2 lakhs of rupees, or between four and five times as much as the Government has expended in the destruction of these animals, and this loss is calculated to be annually recurrent, though readily terminable by the sanction of adequate rewards. Looking at the loss in Cuddapah 2,632, and South Canara 1,765, worth, respectively, Rs. 40,640 and Rs. 35,300 to the

agriculturist, against Rs. 2,529-8-0 and Rs. 5,400 expended by Government, it would seem a retrograde policy to have reduced the rewards formerly sanctioned. In these districts, at least, where it is clear that the cultivators have had to pay for the maintenance of these wild beasts seventeen and six times, respectively, what the Government have laid out on their destruction, and have had to pay this much in cattle alone without taking note of their loss in sheep and goats, it would seem that the Government reward should be enhanced, and that the amounts suggested in Board's Proceedings in G.O., 4th March 1882, No. 261, are not excessive.

But apart from the three districts particularized as marked instances, the Board are of opinion that it is false economy to go on paying inadequate rewards for a series of years, allowing the agriculturist also the while to lie under unnecessary losses and difficulties, and that it will be much cheaper in the end to enhance the rewards as proposed in Board's Proceedings enclosed in G.O., 4th March 1882, No. 261, and press the destruction rapidly home. Large areas could then be perfectly freed by extirmination, and the cultivators would be saved the additional cost to which they are now put of nightly fencing their cattle in tiger and panther proof structures.

TIN ORE IN THE MALAY PENINSULA.—It appears that in 1882 the exports of metallic tin from Ferak amounted to no less than 7,000 tons, which equals the production of Cornwall; and about 40,000 Chinese are now engaged in mining works there. A French Company has been formed for working the deposits of tin ore in Malacca.

INFORMATION has been received from the Foreign Office, through the Science and Art Department, to the effect that the "International Exhibition of Machinery and Apparatus best adapted for the Extraction of Water for Irrigating and Cattle-watering Purpose," announced to be held at Cagliari, in May, has been postponed until November next. The machinery and apparatus admitted to the show are to be divided into the following classes:—Class 1. Boring apparatus of tubular wells furnished with the respective suction pumps. Class 2. Borers and exploring implements for the search of subterranean waters. Class 3. Water-wheels, chains, with buckets for raising water, turbines, centrifugal pumps, hydraulic rams, Archimedes' hydraulic screws, pumps, and water-raising machinery of every description. Class 4. Irrigation plans which are recognised of practical execution and economic utility in Sardinia. The prizes assigned by the Minister of Agriculture are:—For the first-class, one gold medal and the purchase by the said Minister of two apparatus of the system which obtains the first prize, two silver, and two bronze medals. For the second-class, one gold medal, two silver and two bronze medals. For the third class, two gold medals, four silver and four bronze medals. The Minister of Agriculture will purchase, besides, some of the awarded machinery of this class, reserving to himself the selection and disposal of them. For the fourth class, a gold medal, and 500 lire premium.

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The usual Monthly Meeting of this Society was held on Wednesday, the 25th July 1883.

W. H. CORNWELL, Esq., President, in the Chair.

The proceedings of the last meeting held on the 20th of June were read and confirmed.

The following gentlemen were elected as Ordinary Members:—

G. E. Manley, Esq., C.S., Magistrate, Cuttack.

Edward Bigge, Esq., Merchant, Calcutta.

Baboo Ishar Prosad Ganga, of Mohadal.

E. W. Reid, Esq., Manager, Latookajan Garden, Assam.

Baboo Sital Chand Nahar, Azimgunge.

Edward J. Lawder, Esq., Private Secretary, to the Nawab

Vikar-ul-umra, Hyderabad, Deccan.

J. D. Maxwell, Esq., Merchant, Calcutta.

E. A. Samuels, Esq., C. S., Magistrate, Bancoorah.

W. Bleack, Esq., Imperial German Consul, Calcutta.

R. Deey Spedding, Esq., C. S., Collector, Moradabad, N.-W. P.

The Nawab Vikar-ul-umra, Hyderabad, Deccan.

C. A. Sopitt, Esq., Assistant Superintendent of Police, Cachar.

Richard Blechynden, Esq., Junior, Calcutta.

The names of the following gentlemen were submitted as desirous of joining the Society:—

W. Campbell, Esq., Karharrie Factory, Tirhoot,—proposed by the Deputy Secretary, seconded by Mr. J. E. MacLachlan.

A. M. Bose, Esq., Barrister-at-Law, Calcutta,—proposed by Raja Suttayannundo Ghosal, Bahadoor, V.P., seconded by Mr. Richard Blechynden, Junior.

J. R. Croft, Esq., Merchant, Calcutta,—proposed by Mr. G. L. Kemp, seconded by Mr. W. Stalkart.

J. D. Massey, Esq., of Jungipore,—proposed by Mr. R. Blechynden, seconded by Mr. G. L. Kemp.

F. A. Dawson, Esq., District Superintendent of Police, Bancoorah,—proposed by Baboo Pertap Narain Singh, seconded by Baboo Joykissen Mookerjee.

Raja Rajcomar Rai, of Patariaghatta, Calcutta,—proposed by the Deputy Secretary, seconded by Raja Suttayannundo Ghosal, Bahadoor, V.P.

G. B. Reynolds, Esq., C.E., Assistant Manager, Wurrora State Railway Colliery,—proposed by Col. W. B. Thomson, seconded by Mr. J. E. MacLachlan.

Prince Mirza Mahomed Jahali, Bahadoor,—proposed by Rajah Suttayannundo Ghosal, Bahadoor, V.P., seconded by Mr. Richard Blechynden, Junior.

CONTRIBUTIONS.

A large number of Chrysanthemum and Polianthus roots, and some Begonia cuttings. From Baboo Prosono Coomar Banerjee.

Capsicum seeds from General Dhoje Narasingh Rana Bahadoor, Nepal.

Capsicum seed from Masulipatan,—a quantity from E. H. Boileau, Esq., Forest Department.

The *Indian Forester*, Nos. 6 and 7 of Vol. IX. From the Editor.

Proceedings of the Asiatic Society of Bengal for April 1883.

The *Tropical Agriculturist* for June and July (two copies each), from the Editor.

The Records of the Geological Survey of India, Vol. XVI., Part II., 1883. From Government of India.

Suggestions regarding Forest Administration in the Madras Presidency. From Government of India.

The Administration Report on the Jails of Bengal, 1882. From Government of India.

Album Benary No. 7, and a number of large size Floral Pictures. From Ernst Benary Erfurt.

5 lbs. Divi-Divi seeds. From Col. J. Stewart, R.A., Cawnpore.

COMMUNICATIONS.—From Major Pitcher, Department of Agriculture, N.-W. Provinces:—"You would greatly oblige me if you could kindly find out through your correspondents in the Mauritius the prices of the 'grettoise' and of the 'Casse-tête' implements in use there for cleaning and extracting Aloo fibre. I should like an estimate of the cost of each landed in Calcutta." The Secretary said that Major Pitcher's request had been complied with, but there not been sufficient time to receive a reply. The *Casse-tête* is the machine alluded to in late proceedings, the use of which appears to require some practice, but one of the garden men is being trained to work it so that it may have a fair trial.

From Messrs. Egg, Dunlop & Co.—Asking for information regarding experiments made with American cotton seed in India. As such a mass of information has been collected by the Society in the last thirty years during which experiments have frequently been made, Messrs. Begg, Dunlop & Co. were referred to the Society's Journals.

RICE-HUSKER.

Several applications either for drawings or working-models of the Rice-Husker reported on in last proceedings were read; the Deputy Secretary mentioned that these were being prepared.

Information regarding a machine for cleaning and whitening rice has also been received, and will be duly noticed.

MANILLA HEMP EXTRACTOR.

The following letter received from Mr. Wilkinson, British Consulate, Manilla:—

I have the honour to inform you that I have sent to the Harbour Master at Hongkong, with request to forward to you, a model of a Hemp Extractor as used in these islands. The model is reduced exactly one-half the usual size. The several pieces of wood which compose it are packed up loose, but they can be easily put together by means of the enclosed instructions and diagrams. I have had much difficulty in procuring this model from one of the provinces of this island, hence the delay in sending it to you.

The following is a description of the apparatus in use in the province of Albay, Island of Luzon, for extracting the fibres from the stalks of the wild plantain (*Musa textilis*) locally known as Abaca, or Manilla hemp:—

Two strong uprights are firmly fixed in the ground and connected by a cross bar, in the centre of which a large broad-bladed knife is fixed edge downwards on a block of wood fastened lengthwise on the bar; the knife has a strong handle which is connected by a cord to a long bamboo made to act as a spring; by being tied in the middle and the butt parallel and above the bar, the free end thus forms a supple and powerful spring, and holds the edge of the knife firmly against the block; below the bar, there is a treadle, attached by a cord to the handle of the knife; the mode of operation is for the worker to stand opposite the knife, placing either foot on the treadle, which he depresses, thus forcing the knife, handle down and the blade up; he then places a strip of stalk (called locally *aya*) between the blade and the block, leaving only enough to wrap round a stick, on the near side. He then releases the treadle, and the knife, by the action of the bamboo spring, nips the strip firmly against the block, and on the workmen drawing the strip through, the pulp is left behind. The apparatus is extremely simple and inexpensive.

OLIVE IN INDIA.

From Messrs. Begg, Dunlop & Co.—"We should feel greatly obliged if you could supply us with some information regarding the cultivation of the olive in India. * * * It seems strange that the cultivation of the olive which has attained to such importance in the country mentioned should be * * * neglected in India. Any information which you can give we shall be glad to receive, as also particulars as to the best mode of propagation." To which the Secretary replied as follows:—

In reply to yours of the 22nd instant regarding olive culture in India, I append an extract from a report furnished by Dr. Rose in the year 1852, the only experiment to extract oil from the wild olive of which I can find any record. This experiment is alluded to by Dr. Stewart in his *Punjab Plants*, published in 1860, and by Dr. Brandis in his *Forest Flora*, published in 1875, as crucial, and as one that proves that oil cannot be extracted in sufficient quantities to make it remunerative. You will observe in Dr. Rose's report, that the fruit was dried in the sun, and altogether treated in a manner which appears to be quite opposed to the Italian practice, where the fruit is collected into small mounds, and the oil, expressed by their own weight, escapes and runs into a receptacle; they are then pressed with small mill stones, and the oil obtained by this method too is of good quality. The fruit is then placed in sacks, boiling water poured over them, and again pressed, the produce being inferior in quality; the oil is then kept in stone jars, and the almy parts allowed to settle; these dregs must be removed, or the oil would become rancid.

I will lay your letter before the Council, and will submit a proposal to make a careful trial when the season arrives.

As regards modes of propagation. There are three methods mentioned—cuttings which appear to strike readily, "driving a stout stake out from a branch" into the ground which throws out roots and grows into a tree, and cutting from a felled tree the wood "between root and trunk" into pieces about the size of a mushroom, taking care that some bark adheres; which pieces are planted, are fit for transplanting in a year, and for removal to the olive yard in three.

There are a great variety of olives valued each for special qualities. I shall be happy to obtain advice from France as to the species which are most esteemed. I may add that the European olive trees imported into Bengal have not as yet flowered.

Mr. Powell, of the Lahore Agricultural and Horticultural Society, in reply to an enquiry regarding the condition of the imported olive trees tried in Lahore, writes that—"the trees grew well enough in good soil, and even made a show of flowering but no fruit; fruit of the size of a pin's head may form, but they invariably drop off." Mr. Powell adds, he thinks, Chumba and the upper Sutlej Valley suitable places for the introduction of the European variety. "I have at the Agricultural and Horticultural Garden, Lahore, succeeded in raising native olive stocks from seed, and grafting the European olive on them, but though the grafts take perfectly well, none have been down long enough to test the probability of fruit."

INDIAN WHEAT, AND WHAT ITS FUTURE MAY BECOME.

Towards the autumn of 1882, the Secretary of State for India had instituted a series of experiments, by practical experts, in Indian wheat, thoroughly exhaustive as regards their quantitative and qualitative properties and values, in comparison with those of American and other well known recognized wheats of commerce, and from the analyses of which it is shown that the Indian wheats "afford a larger margin of profit both to the miller and baker than any other." These are such startling facts, they possess so much of interest, not only to members of this Society, but to the public generally, that I feel too great notice and prominence cannot be given to them, so I unhesitatingly give, in *extenso*, the whole of the details of those experiments, the results, and the deductions to be drawn therefrom, as published in the *Economist*, 19th June 1883.

That article was preceded by the publication of a pamphlet here in March last, known by some as the "yellow pamphlet," entitled "Indian Wheat versus American Protection; or, the Influence of English Trade and American protection on the Development of India," so ably dealing with this subject, that the Government of India were furnished with a copy of it, and received a communication thereon from the Bengal Chamber of Commerce.

It shows the position occupied by India as to supplies for Europe, how the trade could be diverted from America to this country, and the advantages to the Indian ryot and to the English manufacturer that would result. There is the following proof of the quality of the wheat raised, proof that it can be raised, and at prices that will place it on fair competitive grounds, and there is ample evidence of the one thing only that is needed to achieve such results; and that is, cheap communication by the pushing forward of the railways, and the steady growth of their systems.

I understand that the Government of India are using their endeavours to get a reduction of transit rates on all Indian railways, that this is likely to be conceded, and if it is, combined with the active competition for ocean freight, I know of no valid reason why India should not in time supply the whole of what is called the foreign, or imported, wheat into England, which amounts to annually about 56 million cwt., worth 31 millions sterling. Of that quantity about five million cwt., or nearly three millions sterling, went from India.

The question of the probable wheat supply from India is occupying the minds of most thinking men of position and influence in England, and I see no good reasons why it should not go forward, but time will be required to develop it to a much greater extent than known at present; with this data, however, before Government, and the adoption of the progressive policy so

strongly, yet temperately, earnestly, and ably advocated, the results can be but those of golden harvests for this country.

W. H. COGSWELL.

EXPERIMENTS WITH INDIAN WHEAT.

In October last, Messrs. McDougall Bros., of London, were instructed by the Secretary of State for India to institute a series of experiments with Indian wheat, in order to ascertain how they compared as to yield and quantity of flour with American and other supplies. Conditions under which the experiments were to be conducted are thus set forth by Messrs. McDougall:—

I. That we should take a given quantity of each of these four representative Indian wheats, *viz.*—Indian fine soft white, Indian superior soft red, Indian average hard white, Indian average hard red, and manufacture them into flour by the ordinary process of grinding under millstones. Also that we should take similar quantities of the same wheats, and manufacture them into flour by means of crushing between rollers, according to the system known as the Hungarian or roller system. II. That we should take a given quantity of each flour so produced, and manufacture it into bread. III. That we should note the qualities and other characteristics of the flours produced, also of the offals, *viz.*, middlings pollard, and bran. IV. That we should procure the following representative wheats, of fair average quality of the season, as then being sold in Mark-lane market, for the purpose of obtaining results for comparison, deal with them precisely as above indicated, both as regards flour, bread, and offals, *viz.*—English average, American (red winter), American (spring), American average, Californian average, Russian Saxonska, Russian Taganrog, Russian Kubanka, Russian Ghirka, Egyptian Buhl, and Egyptian Saïda.

As none of the Kubanka or Ghirka qualities of Russian wheat could be obtained in London, these could not be included in the tests. Of each of the other wheats specified, however, 5,000 lbs. were taken as delivered from the ship (weight of sacks or bags not included), and subjected to the treatment specified, the operations being carried out in Messrs. McDougall's own mills and bakeries, under the personal supervision of one of the partners of the firm.

The Evaporation and Loss in Milling.—The percentages under this heading, it will be noticed, vary considerably, from No. 11, Russian Saxonska, stones, 0.7; rollers, 0.2; to No. 13, Egyptian Buhl, stones, 5.5; rollers, 5.4. These variations must not be attributed chiefly to the differences in qualities of the wheats, as they arise mainly from the waste and loss that is inseparable from working small quantities on a practical scale; about ten quarters of each wheat were operated upon in these experimental workings, whereas in ordinary milling a "grist" will run from one thousand to several thousand quarters. This will be readily understood, when it is borne in mind that, after the working of each separate wheat by either process, the stones or rollers, hoppers, elevators, dressing silks, &c., have to be swept out, and it is impossible to avoid some waste from this cause. In milling operations it is found there is a larger loss, &c., "unaccounted for," on inferior wheats than upon good wheats, but it does not exceed a total of 1 to 2 per cent. For practical purposes, the items, evaporation and loss, should be taken as obtained by competent millers, namely, four stones, 1 to 2 per cent; from rollers, 1 to 3 per cent, according to the qualities of wheats.

Water used in Bread-making.—The differences in the quantities of water required by each of the flours from Indian wheats per 280 lbs. flour in making them into bread (ranging from 149.6 lbs. to 141.0 lbs. water) is partly accounted for, by the fact of somewhat similar variations in the water absorbed in rendering the wheats mellow for milling.

Weight per Bushel of Wheats.—These experimental workings have brought to light a fact well worth noting, *viz.*, that the rule so generally held amongst wheat sellers and buyers, and thought to be without an exception, that the greater the weight of a bushel of wheat so much higher must it rank as a flour-yielder, and consequently in value, must now be regarded as true only within a strict limit. A high standard of weight for any given cubical measurement is, no doubt, a good criterion as to dryness of condition and soundness of the grain, for any dampness in grain causes it to weigh lighter per bushel or quarter of measurement instead of heavier (a fact which will surprise the uninitiated). But experienced parties will study with interest three columns in the synopsis of the wheats, showing "weight of 100 separate grains" of each wheat, "weight per bushel," and "yield of flour." Taking equal weights of the four Indian wheats, it will be found that No. 3, weighing 60 lbs. per bushel, yielded more flour than No. 1, weighing 64 lbs.; also, that No. 4, weighing 60 lbs. per bushel, yielded more flour than No. 2, weighing 62½ lbs. The reason of this is evident. The four wheats were equally and perfectly dry, and probably would have weighed the same per bushel had the size and shape of the grains of each wheat been the same, but they differ widely in this respect, Nos. 1 and 2 being medium or small, and Nos. 3 and 4 long and arched. Hence the latter will not fill into a measure as closely as the former, leaving larger spaces unoccupied, and causing any given measure to weigh less in consequence. The old rule holds good for wheats, the grains of which in size and shape are similar, but it will only mislead if applied to Indian wheats like Nos. 3 and 4. It was, doubtless, adopted at a period when it was the custom for all wheats to be sold by measure, and for sales by measure it is still a correct guide, but as sales are now made by weight rather than by measure, the rule can only safely be applied within the limits indicated.

The Offals.—This is a subject of minor importance as compared with the yields and qualities of flour and bread, and it is only needful to state that, of the offals included in these returns, the middlings from both systems of milling were worked down to the

quality known on the Mark Lane market as "coarse midds," fair average," the bran to "bran from stones," and "bran from rollers," and the pollard to "pollard, fair average."

Gluten in Bread.—From an economical standpoint, it may be said the nutrition of bread mainly depends upon the gluten, or, in other words, the nitrogenous or albuminous compounds or flesh formers, contained in the flour from which it is produced. The starch would be equally important if it could not be obtained from other sources in as suitable a form at a much cheaper rate—as in rice, Indian corn, and potatoes. But the gluten is not obtainable from other sources, of equal quality and flavour. Hence its special value as a constituent of wheat. Further, upon the gluten in flour depends the elasticity of the texture of the bread, and consequent freedom from density or heaviness. It is generally believed that upon the percentage of gluten in flour depends the yield of bread that may be obtained from it, as illustrated by the Hungarian flours, which are almost unequalled for yield of bread, and rank high in gluten; but this is erroneous, as proved by the experimental workings now under review. It would be found that the flours high in gluten do not produce the most bread, unless, at the same time, they possess a high degree of dryness, for it is upon the dryness of the flour that the yield of bread mainly depends, and not upon the gluten. The two lots of flour from Russian wheats (Nos. 11 and 12) are those which are highest in gluten, yet they do not yield as much bread as any of the four Indian wheats (Nos. 1 to 4), and the difference in yield from the latter would have been still further increased had they not been previously mellowed with water, as noted, before milling; confirming that it is the dryness of a flour that determines the yield of bread.

Another erroneous idea is, that upon the quantity of gluten present depends the height or loftiness of the bread. This would be correct, provided the fermentation of the dough were in all cases carried to a precise degree; but it varies widely, and it will be found the loftiness or height of the bread depends chiefly upon a high degree of fermentation, provided it be not carried to great excess, rather than upon the gluten. This is illustrated by the bread consumed in the London district, which is made from flours rich in gluten, yet is not so high or lofty as the bread consumed in some other districts, which is produced from flours containing much less gluten, the popular taste in London demanding strength, nutrition, and then fair colour, whereas, in the districts referred to, a high degree of whiteness is demanded before nutrition.

THE FOUR INDIAN WHEATS.

In addition to the particulars contained in the foregoing returns, we have to report that to any one experienced in the requirements of the wheat and flour markets of the United Kingdom, and, indeed, of most other countries, it will be evident there is no probability of these Indian wheats coming into demand for manufacture into flour without a liberal admixture of other wheats. They all possess in a marked degree the same characteristics of great dryness, and a distinct heavy and almost aromatic flavour, inseparable from wheats grown in the climates and soils of the tropics. Also the flours are ricey, the texture of the bread is too close, and the crust is hard and brittle. But these characteristics do not detract from their usefulness in any important degree. As is well known, a miller cannot show skill in his craft to greater advantage or profit than that with which he selects his wheats, and mixes his grists, so as to produce to best advantage a flour from which bread can be made of the colour, bloom, strength, and flavour desired, and withal a good yield.

We pronounce them to be exceedingly useful wheats, in fact, hardly equalled for what is deficient and wanting in the English markets by any other wheats. Their chief characteristics are just those in which the wheats grown in our variable climate are most deficient. Their great dryness and soundness render them invaluable for admixture with English wheats that are in any degree out of condition through moisture, and the great proportions of the wheats harvested here have been in that condition for some years past, a condition that must prevail in all other than that of wheats harvested and stored during fine and favourable weather; and this the English farmer knows, greatly to his cost, is a state of climate that is by a long way the exception rather than the rule. Added to their dryness, the thinness of the skins of these wheats, and consequent greatness of the yield of flour, must always place them in the front rank as a "miller's" wheat, whenever they are handled with reasonable intelligence and skill.

Such unprecedented yields of flour, as shown by these wheats, ranging (by ordinary grinding) from 77.46 to 80.52 per cent against English 65.2 and American spring 72.2, speaks volumes in their favour, and their value is still further increased by another point of merit of almost equal importance, *viz.*, a larger percentage of bread may be obtained than from any other of the flours included in this review.

That, for the best of these Indian wheats (the fine soft white), on the day they were valued in Mark-lane market, a price was offered as high as that for American winters, New Zealand or English (see list of values in synopsis) proves that the great value of the Indian wheats is becoming recognised here, a knowledge that will ere long extend to all our markets. The other lots of Indian (Nos. 2, 3, and 4) were lower in value to the extent of 4s. to 8s. per quarter, as might almost have been expected from the difference in colour and other characteristics; still, as these latter wheats become better known here, this difference in price will be somewhat lessened. Their heavy flavour is not a serious obstacle, as fair average deliveries, when well cleaned and properly dealt with, can be employed in the proportion of 25 per cent to 50 per cent along with home-grown or other wheats, such as Americans, possessing a fine sweet, milky, or nutty flavour.

Glancing at all the facts here elaborated, it is evident that these wheats afford a larger margin of profit both to the miller and baker than to any other.

We venture to record a conviction we have long held, strongly emphasized by the results of these experimental workings, of the measureless importance of the great resources of the Indian empire being developed to the utmost in producing wheat for this country. Farmers here are finding that to live they must produce beef and mutton rather than grain, hence the greater need of resources of supply under our own control.

It is evident such a conviction is common to the members of your Honourable Council, as testified by their unceasing efforts in this direction. And we desire heartily to congratulate them upon the important fruits arising from their labours. The character and general excellence of the Indian wheats are improving with the deliveries of each successive season. The Indian wheats now specially under review were delivered to us in excellent condition (see details) with freedom from dirt (except lot No. 3), barley, gram, and other impurities, also with a freedom from weevil, rarely equalled by Indian wheats, except the prime parcels of the past season, and there is no doubt an outlet in this country and the European continent for unlimited quantities, at prices that shall prove remunerative to all parties concerned, either in their growth, transportation, or conversion into flour and bread.

GARDEN.

The Garden Committee's report was read; they intimate that a new catalogue of plants is in course of preparation, which will be ready at an early date, when a copy will be sent to each member.

The usual Monthly Garden Report was then read.

Since the last meeting good progress has been made in garden work.

A great deal of labour has been taken up in the levelling of the large lawn; however, advance has been made, and the work, when completed, will be a permanent improvement, and will add greatly to the general appearance of the garden, and render it more attractive to visitors.

Hoeing and breaking up the ground throughout the orchard has been commenced, a very necessary though troublesome piece of work, which it will take some time to do thoroughly, as it covers a considerable piece of land.

In the last garden report it was mentioned that a potting-shed was under construction for work during the rains; this has been completed and has been of great use during the heavy rains we have been experiencing in the month under review.

A bamboo fence, some seven feet high, to enclose 150' x 75', including the propagating-shed, is being made, and will be finished in the course of the month; when the fence is covered with creepers and closed with a door, there will be a good and secure place in which to keep the more valuable plants; the want of which is now greatly felt. The material for this useful work is supplied entirely from the garden.

The few Amber cane which germinated, are now in flower, they were sown on the 29th of May, and have thus taken only about sixty days to mature, so this variety of Sorghum is well named the Early Amber. It is proposed to try another crop of cane in the same land, a report of which will be duly given.

The instructions given by the Garden Committee in reference to collecting plants, near and around the plant house, are being carried out, and a road has been commenced which they pointed out as desirable.

A portion of the lane leading into the garden on the eastern side has been widened and the clearances made round the house formerly allotted to the Gardener, now occupied by the Deputy Secretary, give that side of the garden a more pleasing and ornamental appearance.

Propagation is being carried on vigorously, and the stock of plants has thus been largely increased. The following are still available:—

Mahogany, Coffee, Teak, Ceara Rubber, Paper Mulberry, Sago Palms, Polciniana Regias, Sissu, Sivistonia humilis, and other Palms.

Flowers have on several occasions been supplied free of charge to many charitable institutions on application.

RICHARD BLECHYNDEN, Junior,
Deputy Secretary.

OFFICIAL PAPER.

PRICKLY-PEAR AS A SHELTER FOR TREE-SEEDS.

IN accordance with the official memorandum of Government, Collectors were called upon to report the result of any experiments, made by them in the direction, suggested by Mr. H. S. Thomas, of using prickly-pear as a shelter for tree-seeds when sown broadcast amongst masses of it.

The Collectors' replies are now submitted to Government with the following remarks:—

In Anantapore, South Canara, Ganjam, Kurnool, Malabar, Nilgiris, Tinnevely, and Vizagapatam, there is happily no scope for the experiment, as the cactus is either scarce or altogether unknown.

In several districts where tree-seeds have been sown broadcast, sufficient time has not elapsed to allow any seedlings, which may have sprung up, to show themselves above the prickly-pear. This applies specially to Nellore, Coimbatore, Trichinopoly and Salem; and probably to North Arcot, Kristna and Chingleput, where experiments on a limited scale are reported to have failed. It is to be regretted that (except in the case of Nellore) the Collectors have

not furnished definite information as to the areas dealt with, or as to the kind, quantity, and cost of the seed sown, and of the labour employed, as to gauge the results by outlay.

In Bellary and Tanjore, no experiments had been made when the reports from these districts were submitted, but the Collectors promise that experiments shall be instituted at an early date.

In Cuddapah, over 1,300 plants are said to have risen from some tamarind, margosa and jambur (*Eugenia jambolana*) seed sown by the General Deputy Collector in six villages. Information is wanting as to the quantity and cost of the seed used, and as to the approximate area over which it was scattered, and the cost of scattering.

In Madras, it is said that there are no dense clumps of prickly-pear, except in the Molur Taluk. Some margosa seed was sown amongst it in this taluk without result. Particulars as to quantity and area are wanting.

The Collector of Godavari reports that in that district, prickly-pear is chiefly found in and near village-sites, "where its presence is a nuisance which ought to be got rid of." But as it is not got rid of, it should be utilized till it is. It is believed that, apart from the trouble attending its removal, the villagers in some places are very loth to see it destroyed attributing the saving of their lives to it in no small measure in famine, as the cactus bears edible pears in the severest drought. This was notably the case in Coimbatore. The consumption of the fruit by human beings accounts for its propagation chiefly in and around village-sites. While, therefore, this experiment need not interfere with the removal of cactus when it is desired to remove it for cultivation, or because of the harbour which it possibly gives to snakes in villages, so long as it is left standing, it should be utilized as a conservator of trees. In twelve villages some casuarina, tamarind, mango, margosa, palmyra, and date seeds were sown. The casuarina seed did not germinate, possibly from having been carried off by ants, as has been found the case elsewhere. Why the palmyra and date should have failed, is not mentioned; possibly they have not yet had time to germinate, as these seeds seldom show above ground for about a year, and sometimes lie inert but alive in the ground for two or three years till there is a good rainfall. A few tamarind, mango, and margosa seed germinated, but on the whole the result of the experiment does not seem to have been thought encouraging. The Board believe the chief thing wanting is time. They notice, however, that "twenty mango and twenty tamarind trees" are spoken of as "planted" in one place. The planting of grown trees is no part of the experiment, and similar misunderstandings in other places may perhaps account for the want of a greater proportion of success.

In Nellore, the experiment has seemingly been very thoroughly tried and certainly on a large scale. In the Gudur Taluk, 1,183 measures of tree-seed and 1,650 palmyra kernels were sown over 527 acres of prickly pear. Sufficient time had not elapsed to judge properly of results, but none of the seed had germinated at the time of the Collector's report. In the Atmakur Taluk, 1,810 measures of seeds were sown over 112 acres. A few saplings are reported to have been seen amongst the cactus; but as more than two years had elapsed since the sowing, the Collector believes that the bulk of the seed did not germinate. In the Kandukur Taluk, 27 acres were sown in 1880 with a "very large" quantity of seed, and after two years, eighty saplings was the apparent result. In the Kanigiri Taluk, 1,080 measures of seed and 1,000 palmyra kernels were sown over 120 acres in twenty villages. From this seed, 890 seedlings of sorts and 341 palmyras have germinated. This is the greatest success that the Collector can chronicle, and he considers that "as a practical measure to be taken into consideration in the operations of the Jungle Conservancy Department, the experiment stands condemned."

In Trichinopoly, some margosa and tamarind seed was sown broadcast in more than seventy villages, and as the result of this sowing, 364 tamarind and 1,886 margosa seedlings are said to have already sprung up. The Collector thinks the experiment a success; but it would have been more satisfactory if the value of the seed and labor expended had been stated, so that returns might be compared with the cost.

In South Arcot, the plan advocated by Mr. Thomas is stated to have been practised ever since 1874 by the Deputy Conservator, Mr. Woodbridge, who, while adding certain interesting differences of opinion founded on experience and printed in G.O., 14th August 1879, No. 1702, and Board's Proceedings, dated 20th April 1882, No. 1135, says "there can be no doubt of the results of the system," and gives as results 6,257 seedlings above one foot in girth and 31,422 less than one foot in girth, remarking in one place, "self-grown now like a top." He also utilizes dense beds of dwarf wild date in the same way. Mr. Woodbridge adds that in his experience the increased shade and moisture from the growing trees has been found to destroy the cactus in time—a view held also by Mr. Stevenson; and as it is ordinarily found that in thickly-grown wood, grass is exterminated, it may well be that in course of time, the same result will follow in cactus. That the cactus does not suffer under single trees under which it still gets all but the midday sun, is no evidence that a plant which lives so much on sun and air will not die out when thoroughly shut in by a thick top, such as Mr. Woodbridge has raised in it. It will probably then be found to live only as a fringe.

The Collectors (Vizagapatam excepted) have not dwelt on the question of employing prickly-pear to protect avenue seedlings. In Vizagapatam, the Local Fund Board declined to sanction the experiment on any of their roads, on the ground that it would spread the growth of a pernicious pest. Probably this would be the view generally taken, and it may be remarked that, while the idea finds place among the papers circulated, it was neither Mr. Thomas's proposal nor the Board's recommendation that the cactus should anywhere be propagated for the protection of avenue or other trees, but merely that, where it was found to be in existence,

it should be utilized in place of being looked on as an unmitigated evil.

Some reports are meagre, and Mr. Maclean's particularly so. He will now report what measures he has taken for broadcast sowing seed in cactus, and the time of sowing.

Looking to the markedly successful results obtained by the Deputy Conservator, Mr. Woolridge, whose reports are worthy of perusal, the Board are disposed to think that the want of success in other parts may be attributable in very great measure to want of time for the appearance of the saplings above the cactus where it is 5 or 6 feet high, and perhaps also in a less degree to ill-selection of the time for sowing, so that the seedlings did not get the whole rainfall, or to season, and in some places, seemingly, to misunderstanding. Considering that the experiment is not expensive, the Board would wish to see it renewed.

SELECTIONS.

THE POONA RAYAT'S BANK.

PAPER BY SIR WILLIAM WEDDERBURN, BART.

I PROPOSE to-day to lay before you a statement of what has been done up to date towards establishing Agricultural Banks in India; and my object in doing so is to ask for your help in obtaining for the undertaking the support of the English public. We may safely assume that all who come to a meeting of this Association are well-wishers of India. And on the present occasion I am the more encouraged to count upon your active sympathy, because of my past experience when discussing this question of Agricultural Banks. As regards no other proposal have I found so general an unanimity among people of various shades of opinion. All agree that the financial position of the Indian rayat is not what it ought to be, and might be; and all agree that arrangements are urgently required for supplying him, on reasonable terms, with the capital without which cultivation cannot be carried on. I shall therefore, without further preface, proceed to consider the question in its business aspects, setting forth the facts of the case and the considerations which will, I think, satisfy the investing public that the undertaking rests upon a good commercial basis. Though land banks have prospered in other countries they are new to India. We have therefore felt, in approaching the present undertaking, that the first thing to be done is to acquire a certain amount of local and special experience by observing the actual working of such an institution in India. And this it is proposed to do by starting an experimental bank, under good local management, upon a limited scale and within a limited area. For various reasons the Poona District has been selected for the experiment; and the system followed will be that which has been found most successful in practice elsewhere, modifications being gradually introduced as experience may suggest. When trustworthy facts and figures have thus been collected, we shall know what rocks and shoals are most to be avoided, and we shall be in a position to decide in what direction, if any, a business of this kind can be safely and profitably extended.

In order to make the situation clear I will deal with the subject in the following order:—(1) I will give a brief sketch of the Dekkhan rayat's position, with special reference to his dependence on the moneylender, and his financial difficulties in consequence of the exorbitant rate of interest he now pays. Next (2) we may notice what has been done in other countries, Germany, Italy, Australia, Egypt, in the matter of Agricultural Banks. I will then (3) show how it is proposed to apply a similar system in the case of the Poona experiment. And in conclusion a few observations may be added as to the advantages and disadvantages of India as a field for enterprise of the present kind. In dealing with these several topics I will be as brief as possible, being anxious to leave ample time for discussion, and for the criticisms and suggestions with which I trust we may be favoured.

(1) *The rayat's dependence on the money-lender.*—In order properly to realize the important functions which capital has to perform in the rural economy of India, it is necessary to have a clear view of the peculiar position of the cultivator. In the Dekkhan the arrangement is a sort of partnership between the rayat, who is a peasant proprietor, on the one part; and the village saukar, who is the local capitalist, on the other. The rayat owns the land and the cattle, and supplies the labour by himself and his family. On the other hand the saukar maintains the whole party until the harvest becomes available, and provides cash to pay the Government assessment and for incidental expenses, as when a bullock dies or when a marriage has to be celebrated. He also generally supplies the seed corn. The crop thus obtained is shared between them; and this arrangement is a fair one, seeing that any profit that may accrue is the result of the rayat's labour and the saukar's capital. To use the words of Lord Cranbrook, the existence of the money-lender in the village polity is as essential as that of the ploughman. Now this customary dependence of the rayat upon the village saukar must be constantly borne in mind when dealing with any question of the present kind. For the connection is not a temporary or exceptional one produced by accidental causes, but is permanent and necessary, the co-operation of the money lender being to the rayat one of the conditions of his existence. And this fact was strongly insisted on by the speakers in the great debate at Simla in 1879, on the Dekkhan Agriculturists' Relief Act; Sir John Strachey pointing out that "money-lenders are obviously as necessary to the Indian agriculturist as the seed which he sows, or as the rain which falls from heaven to water his fields." There is, in fact, no doubt that the rayat needs the

saukar's help. But it is always possible that this help may be purchased too dear; that in the division of the partnership profits, capital may get too much and labour nothing at all. And this will be the case if the rayat pays a higher rate of interest than the profits of cultivation warrant. Now in the Dekkhan the ordinary monthly rates of interest are 1, 2, and 3 per cent, according to the credit of the borrower; that is, the rayat with good credit can get money at 12 per cent. per annum; the man of middling condition pays 24 per cent; while 36 per cent, and even more, is demanded from the man who needs money badly. For the average borrower we may take 24 per cent as the rate. And it is quite evident that no system of agriculture can pay if burdened with such a charge upon the capital employed. What would an English farmer say to such a drain upon his resources? In order to meet punctually a charge of 24 per cent, the profits of a business must be not only abundant but also regular. And the profits of cultivation cannot be regular when they depend upon the Dekkhan rainfall, which is proverbially uncertain. As yet irrigation has been but little extended; and as regards unirrigated land we are told on authority that the cultivator "hardly gets a full crop once in three years." The return cannot therefore be regular. Again, compound interest mounts up if, owing to bad seasons, payments fall into arrear. And finally, when the debtor gets into serious difficulty he is sued in the civil court which, as we all know, is an expensive process. For a claim of Rs. 100 court fees of sorts amount to about Rs. 25, and there are besides heavy incidental costs, all of which ultimately fall upon the debtor. Under these circumstances we cannot wonder that one peasant after another becomes embarrassed, and that having once stumbled he finds it hard to get upon his feet again. Indeed the wonder is how the rayat can maintain himself at all. And that he does so shows how bravely he carries on the struggle, and how deeply he is rooted in the soil. May we not hope great things from him if he were less heavily weighted, if, for example, he could get his capital at 8 per cent, instead of at 24 per cent, with costs and compound interest in addition? And indeed when we come to ask the question, Why should the Indian peasant be thus left unaided to carry on so heart-breaking a struggle, there is no good answer to be given. In former times when each Indian village was an isolated community, when all the villagers had to draw their loans from the slender store of one local lender, it might be reasonable that they should pay 24 per cent. But it is no longer reasonable now, when communications have been opened up, and when the Indian landholder can have access to the accumulated capital which in Europe is anxiously seeking channels for safe and profitable investment. It is as though on the one hand we had a rich but thirsty soil: on the other hand vast stores of fertilizing water. What we need is a channel of communication in order to benefit all parties. The problem is a simple one. All that is wanted is a little enterprise and a little organization.

(2) *Agricultural Banks in other countries.*—Now, when we propose to establish an organization we naturally look to see what has been done elsewhere under similar circumstances. And fortunately we have examples before us in Europe of popular land banks which have been in operation for many years, and are still spreading with the greatest benefit to all concerned. Land banks, under the name of mortgage debenture associations, were first founded in Prussia by Frederic the Great, and they have attained special development among the peasant proprietors in the Rhine provinces and in Italy. The details of the system and an account of the land credit institutions throughout the continent will be found in a valuable blue book published in 1870, and entitled "Reports from her Majesty's Representatives respecting the tenure of land in the several countries of Europe." Success appears to have invariably attended these financial undertakings. Even in Turkey the system seems to have worked well in spite of the ruined condition of the peasantry. Mr. Consul Blunt, speaking of a land bank in the vilayet of Adrianople, reports that the agricultural interests of the country derive great advantages from this institution: the custom, so prevalent among the small farmers, of borrowing money at exorbitant rates of interest in anticipation of their crops which ultimately placed them at the mercy of a host of relentless usurers, is fast giving way before the facilities offered by this institution, which enables the peasant proprietor to borrow advances at 12 per cent per annum on very moderate security. The Trustees of these 'National Borrowing Funds' propose lowering the rate of interest to 8 per cent next year. It is an undisputed fact that these funds have very much contributed to place the peasant farmers in some districts on a solvent footing; many of them have not only paid off their old debts, but have also improved their properties. These are the results we should gladly see produced in India by a similar system; and, as a nation, we are surely in honour bound not to be behind the Turk in a matter of this kind. I now hold in my hand copy of a paper, "De l'organisation du crédit agricole," recently read by the eminent economist, M. de Laveleye, before the Belgian Agricultural Congress. In this paper he brings up to date the facts and figures relating to land banks, and specially commends the "Raiffeisen Agricultural Loan Unions" of Germany, co-operative associations of peasant proprietors which sometimes comprise whole villages and districts. Next to Germany comes Italy in the development of these popular land banks. In 1880 they were 133 in number, the subscribed capital being about 42½ millions of francs. Their loans had then reached 122 millions, and they had 100 millions of deposits. In the Australian Colonies the system of mortgage banks seems to have specially prospered, yielding dividends of from 15 to 25 per cent to the shareholders. The experience in Egypt is also encouraging, especially as regards India. For there two companies, one English and one French, have been working with considerable success; and the position of the Egyptian cultivator bears a close analogy to that of the Indian rayat. As

regards the method of doing business, it will of course be understood that all these institutions carry on their loan operations with borrowed money. The secret indeed of their financial success depends upon keeping down the amount of their own paid-up capital upon which a dividend has to be earned, while making their loans to landholders out of capital borrowed from the general public at low rates of interest. In this way a small margin of profit on each transaction will, upon a large business, yield a handsome dividend to the shareholders. The methods by which the required capital is obtained by banks and credit companies are various. A large amount is obtained in the form of deposits, either at call or for fixed periods. But a still more convenient mode of raising capital is by the issue of mortgage debentures, a system originally borrowed from the Prussian institutions already referred to and in England regulated by the Mortgage Debenture Acts of 1865 and 1870. As some present may be not familiar with the process, I will briefly explain how the system is worked. Let us suppose that A, a landholder, wishes to borrow £1,000. He goes to the Credit Company and executes a mortgage on his estate, and the company advances him the £1,000 on being satisfied that his title is good, and that the value of the land exceeds at least by one-third the amount advanced. Similarly, B and C execute mortgages for the sums they require, say £2,000 each. The law now allows the company to deposit these mortgages with the Registrar of the Government Offices of Land Registry, and to issue mortgage debentures, say 100 of £50 each, to an amount not exceeding the sum total, in this case £5,000, of the mortgages of A, B, and C; each of these £50 debentures being charged not only on the aggregate estates of A, B, and C, but also upon the whole property of the company, including the reserve fund and unpaid subscribed capital. The debentures are issued for fixed periods, and are transferable by endorsement; they carry interest, payable half-yearly, by coupons, and summary powers are secured to the holder for the immediate recovery of all arrears of principal or interest. Such mortgage debentures, being a very convenient form of investment, are readily taken up by insurance companies, by trustees, and by private investors; and, being secured upon the whole property of the company, they are placed on the market at a rate of interest below that which is demanded from the private borrower. The company thus occupies the position of a credit institution between the landholder, who wishes to improve his estate, and the general public who wish a safe investment without the trouble of inquiring into titles. And the profit for these good officers consists of the difference in the rates of interest: A, B, and C borrowing, say, at 5 per cent, while M and N, the investors, are willing to lend to the company, say, at 4 per cent. To illustrate the process still further we may take the figures of an institution of this class, the Land Securities Company (Limited), incorporated in London eighteen or twenty years ago. The subscribed capital is £1,000,000, of which only £100,000 are paid up. From the returns made in conformity with the Act, it appears that up to March 1881, the amount advanced was about two and half millions sterling. The whole of this sum, except about £10,000, had been borrowed by the company on mortgage debentures. If therefore we suppose that the company took a profit of 1 per cent on these transactions, borrowing, for example, at 4 and lending at 5 per cent, these figures would represent a gross profit for the shareholders of £25,000 per annum, equal to 25 per cent upon the paid-up capital of £100,000.

(3) *The history of the Poona experiment.*—For nearly half-a-century the relations of the rayat to the sarkar have exercised the mind of the Bombay Government. It was seen on the one hand that the rayat could not exist without the money-lender, and on the other hand, that by constant borrowing he was falling into hopeless debt. The problem was how to supply him with capital without the loan becoming the cause of his ruin. As long as the private lender is left uncontrolled, he evidently goes on lending as long as it is profitable to himself, regardless of the consequences to his debtor. It became therefore the idea of the rayat's friends to organize a financial institution which should deal on some recognized principles compatible with the rayat's well-being, instead of leaving him to the tender mercies of hungry and competing creditors. The rayat is in India the goose which lays the golden eggs: a good and patient bird which will lay enough for all if properly cared for. The object is not to let him be torn to pieces in a struggle for his flesh and his feathers. In 1880 a proposal was brought forward by Mr. Jacob, of the Bombay Civil Service, to establish agricultural banks in the Dekkhan, and upon the correspondence the following resolution was recorded in its favour by the Government of Lord Elphinstone:—"In all countries where landed property is much sub-divided, the majority of the peasant proprietors are overwhelmed with debt, and it is notorious that in India the ryots are cheated and oppressed by the money-lenders. His Lordship in Council therefore cannot but think that any loan bank which advances money to the ryots upon fair principles and at a reasonable rate of interest should be encouraged, as tending to keep down undue exactions, and as furnishing an industrious ryot with means to dig a well, or otherwise improve his land." Nothing practical however was then done. And the silent struggle between the rayat and the sarkar did not receive special notice until the subject was forced upon the public attention by the serious agrarian disturbances of 1875, when the chronic antagonism of the classes broke into open hostility. The Dekkhan Riots' Commission was then appointed. And in 1879 their report resulted in the legislation known as Mr. Hope's Act; the chief feature of which was to "disarm" the creditor, by taking from him the power of recovering debt by imprisoning his debtor and selling his land in execution. Now, though these provisions at once put a stop to the severities of creditors, it cannot be said that they do

anything directly towards supplying cheap capital to the rayat. On the contrary, by damaging his credit with the capitalist, they tend directly to increase the difficulty of getting loans on favourable terms. Indirectly, however, the Act has no doubt done something towards a solution of the problem, by driving the native capitalists to devise some means by which their business may be carried on under the altered conditions; by inducing them to join the movement for the establishment of a central institution to be carried on upon sound principles and under first-class management. In this idea they were encouraged by those who took an interest in the scheme on public grounds. And accordingly in March, 1881, a rough project for an agricultural bank was drawn up under the auspices of some leading capitalists in Bombay; and the Hon. Mr. Maudslayi undertook to introduce in the Local Council a Bill for its due incorporation, supposing that Government agreed to the concessions which were considered necessary for the success of the scheme. Among the concessions asked for, two of the most important relate to the settlement of the rayat's old debts, and to the method by which the advances of the bank are to be recovered. It is evident that the bank cannot safely deal with a man oppressed by an incubus of paper debt, even the amount of which is not known, and against whom creditors hold bonds and unexecuted decrees. To make fresh advances under such circumstances would be to put materials into a quicksand. And a settlement of the old debts is absolutely necessary before we can have a firm foundation upon which a solid business can be built up. Such a settlement might perhaps be effected privately by gradually buying up the debts, but this would be a difficult and tedious matter, and besides claims might be held back. Accordingly it was represented to Government that this settlement would best be effected by means of a commission acting under legislative authority. And it was also pointed out that such a liquidation formed part of the original scheme of the Hon. Mr. Hope for the relief of the distressed districts. I am glad to say that the Government of India have responded in the most liberal spirit to these representations; agreeing to carry out a voluntary liquidation by way of experiment in one division of a Dekkhan district in the way proposed. They have also agreed to advance the cash necessary to compromise the claims, the amount to be collected from the rayats in moderate instalments over a term of years. A similar liberal spirit has been shown as regards the collection of the bank's future advances. It is in the interest of all parties, the rayat, the bank, and the Government, that the process of recovering agricultural advances should be effective, cheap, and expeditious. Hitherto in case of default they have been collected through the Civil Courts. But experience shows that this method involves the maximum of friction with the minimum of result. Government have therefore agreed that the bank's advances should be treated as advances made under the Land Improvements Act, and recovered when necessary through the revenue officers of the district and village, instead of by the machinery of the courts and bailiffs. This is the system followed in Germany where the bank's advances are recovered with the land tax. And it seems a reasonable one, as the bank will in fact be carrying out, through private enterprise, a duty which those Acts seek to perform by departmental agency at the expense of the State. The policy of Government on these important questions was announced in November last by the Hon. Major Baring in his speech on the Bill to amend the Land Improvements Act. He on that occasion explained that Government wished as far as possible to improve the system under which agricultural advances from the Treasury were made and recovered under the Act, but that they hoped much more from the encouragement of private enterprise. He then specially referred to Agricultural Banks, and stated the concessions above set forth. This very encouraging announcement naturally gave great heart to those interested in the scheme. Meetings were held at Poona, and a committee formed; and on the 23rd of November last an influential deputation of leading capitalists waited on H. E. Sir James Fergusson at Government House, and set forth in some detail the arrangements which according to their experience would be the best in order to establish an experimental bank in the Poona District. They proposed that the experiment should be tried in the Purandar Taluka or sub-division, and that the capital of the company should be Rs. 10,00,000 in shares of Rs. 500 each. In reply to this address, H. E. expressed his sympathy with the movement, and mentioned that he had personal experience of similar institutions in the Australian Colonies, which had been very successful. He referred specially to one in New Zealand whose working capital was three millions sterling, which had paid a dividend of 15 per cent for many years, and had accumulated a reserve fund of £300,000. Subsequently to this interview, a formal despatch, dated December last, was received by the Bombay Government from the Government of India, and in this are set forth in full the views indicated in the speech of the Hon. Major Baring. A copy of this despatch was supplied to the Poona Committee, and upon this they have given a further detailed statement. These important documents are too lengthy for me to attempt to summarize them within the limits of the present paper. But I have had them printed in a convenient form, and shall be happy to supply copies to those interested in the undertaking.

We have now dealt with the three points indicated at the commencement of this paper—(1) the rayat's dependence on the moneylender; (2) Agricultural Banks in Europe and elsewhere; (3) the history of the Poona experiment. And there only remains to make a few remarks as to the general prospects of the scheme. I will therefore conclude by noting what appear to be the special advantages of India as a field for such an enterprise. I will also candidly admit the special difficulties; pointing out how it is proposed that these should be met. Among the leading advantages in India I would mention (a) the large margin of profit from cultivation

when capital provides irrigation and manure; (b) the merits of the rayat as an honest debtor; (c) the existence of a skilled agency for money-lending; and (d) the favourable attitude of Government. (a) As regards the possible profits of Indian agriculture under favourable circumstances, I only wish all present could witness the almost magical transformation effected round the city of Poona by means of water and manure. Ten years ago this land produced only a ragged crop of millet, worth perhaps Rs. 5 or 10 an acre, and dependent for its existence on the periodical rains. Now the same land is covered with a magnificent crop of sugar-cane, and when I left Poona the other day it was being sold as it stood on the ground for about Rs. 500 an acre. This is simply the result of capital, the landowners in the immediate vicinity of Poona being men of some means who could afford to take water from Fife Tank and "poudrette" from the Municipality. No doubt the price I have mentioned was exceptionally high, the cane being retailed in the city by way of a sweetmeat. Such a price could not of course be maintained if sugar cultivation was largely extended in the locality. But I mention the example as coming under my personal observation. Also under ordinary circumstances the net profits of sugar-cane are estimated at from £10 to £20 an acre, the cost of cultivation being about Rs. 100 per acre, while the crop does not soil for less than Rs. 200 or 300. Nor is sugar-cane the only profitable garden produce. In the neighborhood of Poona we find extensive spice plantations and vineyards with orchards of mangoes, plantains, and oranges. The rayat is also becoming a considerable grower of potatoes, carrots, and so forth. Indeed, throughout India we find that with capital at his back the rayat can produce any crop for which there is a foreign demand—cotton, wheat, spices, tobacco, jute, oilseeds. For it is the characteristic of India, with her rich soil, varied climate, and skilful "petite culture," that she can produce of the best quality whatever is demanded by foreign trade. Whether it be opium or indigo; rice or tea; coffee, cotton, or tobacco; if she has only time India will always place her products in the first rank among the markets of the world. My proposition therefore is, that in no other country does capital employed upon land give so rich and so certain a return; and that the difference in value between "dry-crop" and "garden," between a precarious crop of millet and an assured crop of sugar-cane, provides an ample margin upon which the capitalist can rely for the safety of his advances. (b) We next come to the merits of the rayat as an honest debtor. He is in fact a model paymaster; being filled with a religious desire to pay his debts, not only those incurred by himself, but also those incurred by his father and even remoter ancestors. To leave ancestral debts unpaid is in his eyes a shameful thing; it is as though he refused to his father due funeral rites. This strong religious sentiment (may it never grow less!) is indeed the sheet-anchor of the rayat's credit. Moreover, he is by no means wanting in shrewdness, and he feels that for temporal as well as spiritual purposes it would be fatal to repudiate his debts; for who would then be found to trust him? Hence his steady refusal to avail himself of any insolvency law. For example, in the Ahmednagar District, with a rural population of nearly three-quarters of a million, not one rayat, out of the thousands hopelessly involved, was found willing to accept freedom under the special insolvency clauses of the Dekkhan Agriculturists' Relief Act. Two or three were indeed declared insolvents by the Courts, but this supposed benefit was conferred on them in spite of their protestations and even tears. I have myself often seen instances of the same feeling. I was especially struck on one occasion when a number of leading rayats, some three or four hundred, had come together to meet me at Sanganner, a local centre of importance in the Ahmednagar District. I asked them how they liked the operation of the Dekkhan Agriculturists' Relief Act, which had then given a sudden check to all process for the recovery of debt. The answer of the principal riyat who acted as their spokesman was given in two words (Maharatta): "Sikh jhala"—"we are in comfort." He went on to explain that now their creditors could not harass them with decrees and executions; so they paid the Government assessment out of the crop, and ate the rest themselves. He then again repeated the words, "Sikh jhala." This seemed to me a very dangerous state of things, looking to the precarious position of the Dekkhan peasant when unsupported by the money-lender; so I said, "I am glad to hear that you are in comfort. But how about the saukar's rupees which you have had? Is it the part of honest men to live in comfort when their debts are unpaid?" To this there was an immediate and unanimous answer in the negative, not only from the spokesman but from all those present. Many of them stood up, saying "No! No! it is not honest. We wish to pay our debts. But we have been oppressed by our creditors, and we do not know how much we really owe them." They then went on to ask that Government should make inquiry and ascertain the true amount of the debts, and whatever that was they would pay it. On this point they were quite vehement, saying: "Allow us and our children dry bread to eat and a cloth to wear, and give everything else to our creditors until our debts are paid." Afterwards they handed me a written proposal to the same effect, which I sent on to Government. I think gentlemen present who have experience of the Indian peasantry will bear me out in saying that a feeling of this kind is very universal, and that the rayat is an honest debtor who is willing to pay if he has the means. (c) And if on the one hand the rayat, on account of his hereditary instincts, is a satisfactory debtor, so on the other hand in the hereditary trading class of India, we find ready an unrivalled agency for the distribution and collection of loans. At present the actual money-lending business of the Dekkhan is in the hands of native saukars, chiefly Marwaris. These local capitalists thoroughly understand their business; in each village they can tell you to a nicety the means and character of the individual rayats; and they are very shrewd, patient, and economical in their management. In starting an Agricultural Bank it would

be fatal to take up a position of antagonism to this capable and influential class. If it is to be a commercial success a bank must secure their co-operation: bringing them in as shareholders, depositors, agents, and brokers; and making it advantageous for them to join heartily in the scheme, and to bring to the bank a portion of their business connection and good-will. The object is not to subvert or set aside the existing machinery for the distribution of agricultural capital, but to organize and regulate it. And I am glad to say that as regards the Dekkhan Districts, we have every reason to be satisfied with the friendly inclination of the local capitalists. Indeed, as already shown, they have actually taken the initiative, under the guidance of a few native gentlemen of special intelligence and public spirit. At first they were naturally inclined to doubt the effect which a large new money-lending institution would have on their interests. But they are clear-headed practical men, and soon came to see that it was for their advantage to have a share in a bank which would enjoy special privileges from Government. They also believe that a stimulus will thus be given to the prosperity of the district and to the general trade which is mostly in their hands. I have already described the active steps taken by the Poona Committee, and I understand that about one-half the total capital required has already been offered from the four Dekkhan Districts. On the subject of the facilities for local control and management it is further of importance to note that the bank may rely for efficient help upon the class of Government pensioners, public servants who have retired after a long term of approved service in the revenue, judicial, and other departments. These men are in every way fitted to serve on local boards, from their high character, from the leisure at their command, and from their experience and knowledge of business. (d) The last point noted is, the favourable attitude of Government. It is an old saying that the English capitalist invests his money in every other country of the world in preference to India; and no doubt the distrust of Indian ventures dates from the old times of John Company, when he did not make private enterprise welcome if it appeared in the persons of "interlopers" and "adventurers." Happily this state of things has long ceased to exist. Yet there still seems to survive in financial circles a certain fear of official jealousy. Thus a couple of years ago a gentleman of large financial experience, and himself a Director of the "Credit Foncier Egyptien," wrote to me as follows regarding the present project: "My impression is, from what you and others have told me, that India has all the conditions requisite for the success of a land bank, provided always it can rely on the support or, at any rate, the 'benevolent neutrality' of the Government." Since this was written the Government of India have declared their policy on the question. And we know that they are prepared to go much further than mere "benevolent neutrality." Recognizing the true interests of the State as the general landlord, they offer to undertake of this kind an active support, administrative, financial, and legislative. And when we remember how all-pervading is the influence of Government in India, we realize how important is the change in the situation when this influence, formerly adverse, is now thrown into the scale in our favour.

When we look upon the other side of the picture, and consider what are the special disadvantages attaching to such an enterprise in India, I do not myself see that, from a banking point of view, there is any real and serious difficulty except that arising from the poverty of the individual rayat and the want of solidity in the security he is able to offer. He is indeed the absolute proprietor of his holding, subject to the payment of the Government assessment; and if this Government demand were either fixed or limited in a definite way, the security would be good; but this is not case, the demand being liable after every 30 years to an enhancement which may swallow up the margin of profit upon which the mortgage depends. The theory no doubt is that the enhancement will not touch improvements made by the holder, and those who support the existing land system that in practice the demand is not increased except on fair and sufficient grounds. But I feel bound to admit that this view of the case is not accepted either by the rayat himself, or by those who would otherwise be willing to invest their savings in land. I make this admission with regret, as being the weak point in the scheme I advocated; but it cannot be denied that the banker must look with distrust on a security the solidity of which depends upon the discretion of the fiscal authorities. Throughout the Dekkhan the original 30 years' leases have within the last few years been failing in, according to the order in which the groups of villages were first settled. Thus in Purandar Taluka, where our experiment is to be made, some villages have been re-settled, others are due for revision, while others again will become due within the next few years. This prospect naturally brings uncertainty into any calculations regarding the value of the holder's interest. The Poona Committee have therefore asked that in the area of experiment the existing rates should not be disturbed for a period of twenty years from the present date. The difficulty may thus be dealt with by a simple departmental order, and it is hoped that the Local Government will not object to make this moderate concession which those on the spot consider essential in order that the experiment may have a fair trial. The other difficulties which have from time to time been suggested to me while Agricultural Banks in India have been under discussion, appear to have been all considered and disposed of: the rayat's old encumbrances will be dealt with by a voluntary liquidation under the management of a Statutory Commission; the native money-lenders instead of being hostile have themselves taken a leading part in the movement for the establishment of a bank; the delay, vexation, uncertainty, and expense of collection through the Civil Courts will be replaced by a summary procedure mainly worked by the village officers, and more suited to the simple habits of the rayats, while, instead of the old official obstruction, the undertaking will be supported by the hearty good-

will of the highest authorities. To conclude, I beg to submit that the facts above set forth show that the undertaking rests on a good commercial basis; and I would ask you to encourage the local efforts made in India by securing for the enterprise some active and efficient support in this country.

AGRICULTURAL EDUCATION.

At these times of proposed agricultural improvements by legislation, the public should not lose sight of another way by which improvement of perhaps a more substantial nature may be brought about—an alteration for the better, which would make the other less necessary. We allude to better training in their respective professions of proprietors, factors, and farmers. A proprietor educated from the time he leaves the nursery at one of the many large public schools, and having bought a right of one of the Universities, by the sweat of his brains for a few years, to write M.A. or B.A. after his name, is no more able to manage his estate than he would be to measure the distance of the sun from the earth without studying mathematics. No doubt his education and associations have made him a gentleman and a Britisher of the first water; but we must have more in these times than that, if those happy social relations which have made Britain great are to continue to exist. Such an one too frequently guided by a lawyer-factor, whose training for the very responsible office he is supposed to fill is often even worse than that of his employer. Of course we have a few noble exceptions in both classes, but it is not those who have induced our remarks. The result is the usual one when the blind lead the blind. It becomes a matter of greater interest when we see that this state of things involves not only farmers, but the public generally, in a serious loss. We are loath to admit the fact, on the other hand, that farmers have not been keeping up to the times as to the knowledge of the very essence of their business.

It was good enough to do as their forefathers did, when good honest dung was the only manure applied to crops, and as many pence per annum would have covered the expense of purchased food as it now takes pounds; but it will not do in these days, when farmers have to look to their interests, involving a sum often far greater than their rents against dishonest manure merchants, culpably negligent seed merchants, and chemical quacks. For some analytical chemists are like other men, and can be bought at a price. We only speak for the few, we hope, very few, of these different classes, but it is usually into such hands that the ignorant fall. No one can read the reports of Dr. Voelcker and Mr. Carruthers, in the last Royal Society's journal, without feeling the truth of our remarks. With all those complications, it is becoming more necessary every day that farmers should educate themselves in the scientific practices of their profession. The absurd notion that 'science' and 'sound practice' in this industry are different things, must die out, and farmers must get to know for themselves in most cases or by the aid of a reliable specialist in a certain few, what is being bought. If a farmer were to go to market to buy a cow, and come home with a bull, because he did not know the one from the other, the act might appear more absurd to farmers, who would all laugh at him; but the mistake would not be greater, and would really cost much less, than that of the man who went to market to buy dissolved bones, and paid £100 for what was said to be such, but which was really dissolved coprolites, mixed with refuse hair, and horn, worth less than £50; or another, who thought he had secured £40 worth of the finest permanent pasture grass seeds, and had only got ryegrass, worth in the open market about £10, and enough weed seeds to keep him in misery for years to come.

Government has of late years begun to do something towards spreading a knowledge of agricultural facts throughout the masses, but as yet all that can be done with present machinery must be very superficial, though in the right direction. We have an agricultural class, subsidized by Government in Edinburgh University, and ably conducted by Prof. Wilson, who is possessed of large and varied experience. Yet we would like to see the Government do more than that. We should like to see a few more colleges on the type of the Royal Agricultural College at Cirencester, but with the staff appointed and paid by the Legislature. It was most unfortunate for the agricultural work that serious mistakes in calculation and management were made in the early days of this college; else we should now have seen the country dotted over with such places, doing an untold good to the community at large. The college was also unfortunate in getting into bad repute through rowdiness on the part of students; and even yet, although no such thing has been experienced for years, we now and then hear the same has not quite died away. A few facts as regards the work and management may not be uninteresting. The institution is entirely self-supporting, having been built by private enterprise. Lectures on agriculture, and the various important allied branches of science, are given by a regular staff of six competent men, besides various auxiliary lecturers who come at intervals. The students, who usually vary in number from 90 to 100, are strongly encouraged to go in for practical work of all kinds, and this is wherein we think the stronghold of the Royal Agricultural College lies. A young man when he leaves school or college is better not to give up all studies which conduce to his culture, although he means to learn to farm as a profession.

The sudden relaxation of strict rule is often too much for the average student. Going on to a farm as a boarder, in the usual way, very generally results in his getting into lazy habits and learning nothing of business, and much that he would in a few years be thankful never to have known. The result is that he goes abroad, having failed to succeed in this country simply because he

neither gave himself nor the country a chance. In connection with the college there is a farm of 500 acres, where students are at liberty to assist in work of any kind, and for excellence in which as well as for practical work done at the veterinary hospital and blacksmith and joiner's shops, there are prizes given. These, in a far greater degree than the real value would induce, encourage in all Englishmen of the right sort a true spirit of healthy rivalry. The college, in short, is one the Government would do well to take a pattern from in many respects. This is shown by the high and yet improving standard of work done, as judged from the results obtained by the students at the two most important recent examinations for the diplomas of the leading English and Scotch agricultural societies, as well as by the largely increasing percentage of passes for the diploma of the college itself, now that the more important subjects are taken by outside examiners.

The Royal Agricultural College has now been before the public for many years, and its rules and management have been discussed from time to time in the columns of some of our contemporaries. These regulations have not always appeared in a favourable light. It must be fresh in the minds of many that very disastrous consequences, to the college itself and to agricultural teaching generally, resulted from the removal of Professor Church, by an arbitrary edict of the Principal, who, according to the rules still existing, has such power of removal. We are glad to know that, under a new Principal, matters go harmoniously with both staff and students; still, we can't help thinking that the appointment should be of more certain tenure. Many former Professors now occupy important positions in the scientific world, and several of the present staff are men of position and ability. If our hopes, that like institutions to this (which has done such good work in the past, and is now, as we have shown, exhibiting increased activity and usefulness), may be founded under Government auspices, should be realized, they may profit by its experience, and frame such a constitution as will work without any possible friction for the good of the cause of increased agricultural education. Most of our readers must be aware that we are likely before long to have a Minister of Agriculture. We hope that one of his prominent functions, or of the officials of the Board of Trade appointed to look after the interests of agriculture, will be to look over agricultural education in all its branches; for, as we stated in our opening remarks, we are confident it is largely by the better education of all the different classes that have to do with land that British agriculture is again to take the position that it ought to occupy in the eyes of the civilized world.—*North British Agriculturist.*

THE ROYAL AGRICULTURAL COLLEGE.

SITUATED near the noble Oakley Park, the seat of Lord Bathurst at Cirencester, Gloucestershire, is a stately Gothic building, standing in the midst of the "College Farm," a mile and-a-quarter from the town of Cirencester, and in the vicinity of the picturesque Stroud valley. This is the Royal Agricultural College, in which so many of the leading agriculturists of the present day have been trained, and in which are at present a number of students who are quite up to the standard of former years. To this establishment I wended my way on July 23rd, with the intention of seeing what facilities are afforded for the training of students, especially young men from India or who are destined to be employed in India. When I was at Cirencester five years ago, the Rev. Mr. Constable was Principal of the College, but he left in 1879 and the reign of the Rev. John B. McClellan, M.A., Double First Classman in Honour, and late Fellow of Trinity College, Cambridge, commenced at the beginning of 1880. To this courteous gentleman's management must, I believe, be attributed much of the success and many of the improvements which have marked the history of the College during the past three years. To him and his assistants and pupils I am indebted for much of the information I give here. It was 2 P.M., when I reached the "R. A. C.," and some of the students, who had been working during the morning, were just starting tennis, cricket, and other games, on the well-kept lawns. Others were still at work in the College, but most of the work is done in the morning. The teaching staff is at present very strong; in this direction there has been much improvement during Mr. McClellan's principalship, resulting in an increase in the number of students. There are now about 90 students, including six natives of India. The professors and instructors include such men as Prof. H. J. Little, M.C.R.A.S.E.; Prof. R. Wallace, F.H.A.S. Agric. Gold Medalist Edin., Diploma R.A.S.E.; Mr. Russell Swanwick, M.R.A.C.; Prof. E. Kluch, F.C.S., F.L.C.; Prof. Allan Barker, F.L.S.; Miss E. A. Ormerod, F.M.S., Consulting Entomologist to the Royal Agricultural Society; Prof. H. Ohm, M.A., F.M.S.; Prof. A. W. Thomson, C.E., B.S.C., Prof. W. F. Garstide, M.B.C.V.S.; Prof. Fawcett, B.L.; Dr. Augustus Voelcker, F.R.S., &c. These, with other competent gentlemen not employed upon the regular staff of the College, form the Board of Studies. The College, with a large mixed farm attached for practical instruction, was established in 1845 under the patronage of H. R. H. the late Prince Consort, with the support of a number of the nobility and gentlemen interested in agriculture from all parts of the kingdom, "for encouraging and supporting the study of agriculture." Under its Royal Charter it has six residential professorial chairs, and grants certificates of proficiency and a diploma of membership and associateship. In 1870, a supplemental charter with new powers was obtained, and in March, 1880, her Majesty was graciously pleased to command that the College be styled the Royal Agricultural College. The object of the institution, in the words of its Charter of Incorporation, is, by combination of College and Farm,

"to teach the science of agriculture, the various sciences connected therewith, and the practical application thereof in the cultivation of the soil, and the rearing and management of stock;" in other words, by teaching the scientific principles which necessarily govern agricultural operations in all parts of the world, together with the methods and processes of sound agricultural practice, to furnish the most efficient training for the professional or business of an agriculturist, whether at Home, in India, or in the Colonies,—a training, that is to say, which shall be expressly suited to the needs and requirements of the following classes:—intending landowners or occupiers; intending land agents or surveyors, land stewards, factors, or managers of estates; intending colonist employees in Indian agriculture, forestry, &c. In addition, however, to affording the best scientific and practical education for all such requirements, the College offers to its students many of the general advantages of a University course. As the institution has a special interest for Indian readers, and will probably be the training ground for some of the Indians and Anglo-Indians of the future, I shall briefly refer to some of the principal features of the College, in order that your readers may form a fair idea of its capabilities.

The Chapel is a neat Gothic structure, and is furnished with an organ, and a reredos erected in memory of the Rev. Principal Haysgarth. The Library contains several hundred volumes, chiefly of the best works on agriculture and the allied sciences, and works of reference. The Reading Rooms are furnished with daily and weekly newspapers, general and scientific, and the leading agricultural periodicals, including one or two from India. There is a Museum divided into special departments for the illustration of farm produce, agricultural chemistry, natural history, geology, botany, building, veterinary science, &c. A considerable space of ground is allotted for the Botanic Garden, which is an adjunct of great value to the College for practical instruction in the botany of agriculture and arboriculture, and various experiments in vegetable physiology. It is divided into numerous plots occupied by representatives of the natural orders, grasses and other agricultural and economic plants, and studded with numerous specimens of shrubs and trees of British and foreign origin. To me this was one of the most interesting parts of the establishment. Here lectures are given upon the spot, with the subjects of the lecture growing before the students' eyes; a plan infinitely superior to teaching from mere books and drawings. The Lecture Theatre is a lofty hall of large dimensions, with tiers of desks capable of accommodating nearly 100 students. In addition to the lecture theatre there are several excellent class rooms appropriated to the lectures of the various professors; and the Library and Dining-room are also used, as required, for the same purposes. On the walls of the Dining-room I noticed a list of Members of the College, by Diploma (M.R.A.C.). This list comprises only those students who have graduated in Honours. It is, perhaps, the best recommendation the College could possess; such names as the following I noticed there:—Henry Tanner, F.C.S. (1847), author of many text books on agriculture and now an Examiner in agriculture at South Kensington; John Coleman, now an Assistant Royal Commissioner on Agriculture; W. E. Robertson (1863), now Agricultural Reporter to the Government of Madras; Charles Benson, Assistant Manager of the Government Experimental Farms, Madras; C. E. M. Russell (1876), Superintendent of Forests and Government Farms, Mysore; Kumar G. Narayan (1880), of the family of H. R. H. the Maharajah of Cooh Behar, Bengal, the first native Indian who obtained the diploma; C. E. O. Wilkinson (1882), Agricultural Director of Katates to H. E. the Nawab of Hyderabad; and E. C. Ozanne (1883), Director of Agriculture, Bombay. In the same year as Mr. Robertson obtained his diploma, Professor Wrightson, F.C.S., Professor of Agriculture at South Kensington, obtained his diploma. In April last, two natives of Bengal, Ambika C. Sen, M.A., and Syed S. Hosain, B.A., obtained diplomas, the former having received the highest number of marks ever given to any student in the College; the latter was only third on the list, Mr. Ozanne being second. The chemical, physical, and biological laboratories are well-fitted with all necessary appliances. The biological laboratory was added in 1881, and is in charge of Professor Harker. It is fitted up after the most approved models, and supplied with efficient microscopes and the necessary instruments, and re-agents for dissections and minute examinations of plants and animals. The *Mail* has on more than one occasion recently advocated the extension of a knowledge of veterinary science in India, and I was pleased to hear that two prizes for veterinary science, one of £50, and the other of £20, are annually awarded to the Bengal Agricultural scholars by the Bengal Government at the final examination. The Veterinary Hospital at the College is fitted up with boxes for the reception of diseased or injured horses; with yards and sheds attached for sick cattle and other stock, examination houses, pharmacy, and shed for post-mortem examinations. The College Farm contains about 500 acres, divided into 20 fields, occupied and worked by a former Honour student and Member of the College,—Mr. Russell Sanwick—who has achieved a high reputation in agricultural circles. I could not see the best of the stock, as they were at the York Agricultural Show. Mr. Sanwick has taken over 300 prizes for his cattle, sheep, pigs, &c.

Of general description I have given enough, I believe, to show that the Royal Agricultural College is admirably adapted for teaching natives of India and others the scientific principles which necessarily govern agricultural operations. In the Report of the Special Committee to the Agricultural Society of Scotland last year, it was stated that "agriculture is now a science, or rather the application of a number of sciences, and requires as wide a range of scientific knowledge as any learned profession. . . . Nothing but a College specially organised and equipped for the training of agriculturists is capable of affording the means of

acquiring the knowledge which is now necessary to the proper understanding of the scientific principles upon which the varied practice of agriculture rests." And now to mention a few items I obtained from the worthy Principal of the College. Questioned as to the Indian students, he produced a photograph of six natives, four of whom were from Bengal, selected by the Bengal Government; one was from Oude, his expenses being paid by the Government of the N.-W. Provinces. There was one who paid his own expenses. All had worked well, and two had left last April. There are now six Indian students, and two more are expected from Bengal soon. The Indians are out-students, and therefore do not take their meals with the rest of the students. They are very studious, and as a rule do not join in the games in which the Europeans indulge. As I expected, they do not, as some of the Europeans do, enter plunging matches and other competitions where the students undertake the actual working operations on small patches of land in order to know by experience what work the farm labourer has to do and how he should do it. About eight months ago, H. E. the Nawab of Hyderabad, with his suite, visited the College, and was so much pleased with what he saw that he observed that he should like to spend a few months at the College as a student, but he had not time to do so. "However," he went on to say, "seeing that I cannot stay here, perhaps you can send out one of your diplomated students to take charge of my estates, and teach the natives how to till their soil better than they do at present." The Nawab remarked that he hoped that Hyderabad scholarships would eventually be established. It was arranged that Mr. C. E. O. Wilkinson, who took his diploma last year, and who is related to Sir Bartle Frere, should go to Hyderabad as Agricultural Director of the Nawab's estates. The last advices from Mr. Wilkinson were favourable. At the close of last year Colonel Pearson, the English Director of the Forestry School at Nancy, France, where many of the Indian forest officers are trained, visited the Royal Agricultural College in order to ascertain what facilities are afforded for the study of forestry, as it is probable that at no distant date the forest officers destined for India will be trained in England. An application was sent to the Government by the R. A. C. authorities with a view to this College being utilised for the purpose, and it was pointed out that there are large woods of various kinds close to the Royal Agricultural College, belonging to Lord Bathurst where all the operations of forestry are carried on. In the forest of Dean (1½ hour from Cirencester by rail) are some of the finest oak forests in the country, so that on the whole this College would be a very good establishment for the purpose I have named. However, a final decision has not yet been arrived at, there being one or two other Colleges where it is said facilities are offered for teaching forestry; Cooper's Hill College being one of them. There are at present some Indian Civil Servants studying at the R. A. College, and one of the professors assured me that "one of our best men is Mr. Koonas, the son of an Indian General." The Principal said, "We have had many nationalities represented here since I have been here; we have had men from India, Greece, Italy, Brazil, France, Egypt, Channel Islands; English, Scotch, and Irish." The late Duke of Marlborough had been President of the College for several years. He will be succeeded by the Duke of Richmond and Gordon, K.G. H. R. H. the Prince of Wales is patron, and the Committee of Management includes such lauded proprietors and agriculturists as the Earl of Ducie, the Earl Bathurst, Sir Michael E. Hicks-Beach, Colonel Kingscote, Professor Story Maskelyne, and the Hon. Lord Lyttelton. I cannot conclude this notice of a most interesting educational institution—which all Anglo-Indians at home or abroad would do well to visit—without mentioning the *Agricultural Students' Gazette*, edited by students at the College. In the number for July 1882, I find an article by Professor Kinoh, on the Soy Bean, which attracted considerable attention in India last year.—*Madras Mail*.

AGRICULTURAL EXPERIMENTS IN SUSSEX.

THE experiments conducted at four different stations—representing different soils—during the past year by the Sussex Association for the Improvement of Agriculture have, according to the report presented by Mr. Thomas Jamieson, chemist to the association, yielded some interesting results. To the surprise of wondering farmers, the barren clay of an abandoned field near Haywards Heath has been made, under the fertilising influence of a suitably combined manure, to give forth a remunerative harvest, and, moreover, valuable knowledge has been obtained on more than one important scientific point. In broad outline the experiments have confirmed the familiar rule that to produce cereal crops, nitrogenous fertilizers are indispensable; to produce roots, phosphatic. For the enforcement of this principle Mr. Jamieson judges even the varied manurial riches of that standard fertilizer, farmyard manure, insufficient. Both at Billingshurst and at Haywards Heath experience has taught him that even a heavy dose of farmyard manure, unaccompanied by artificial fertilizers, cannot supply all that is wanted, and that an addition of the special substances afforded by the several crops adds to the value of the harvest out of proportion to the outlay. It is, on the other hand, quite practicable to supply all the constituents wanted for plant food economically by means of artificial manure alone. Among nitrogenous manures nitrate of soda has, in the past year—possibly owing to atmospheric conditions—carried off the palm. Mr. Jamieson, who wages war most unceremoniously upon various accepted beliefs, protests against the opinion that nitrate exhausts the soil. Add what else is wanted, he says, and the exhaustion

will be nil. He is not careful to appraise nitrogenous manures otherwise than according to their wealth in nitrogen—with this proviso only, that some, as, for instance, sulphate and guano, may under circumstances act to a certain extent injuriously owing to the presence, or generation, of acid. At Hasocks Gate, Mr. Jamieson observed that the sulphuric acid, liberated from a dressing of sulphate of ammonia, so seriously affected a crop of swedes that they assumed a perfectly red colour, as if exposed to the action of acid vapours. This symptom disappeared upon treatment with a dose of nitrate of soda. As regards phosphatic manures, Mr. Jamieson adheres to his former opinion that—except on chalk—it is perfectly immaterial whether the phosphate be applied in a soluble or an insoluble form. Indeed, more favourable results have been obtained from coprolite than from bones. What Mr. Jamieson sets far more store by than solubility is minute pulverisation. His favourite mode of supplying phosphate is in the shape of a mixture of steamed bone-flour and finely-ground coprolite, a moiety of the phosphorus being allotted to each. On chalk soil, such as that at Preston Park, dissolved bones have produced the best result. Nevertheless, the deficiency of phosphorus in the manurial dressings, purposely left deficient in one substance or other, shows a less marked effect on this very soil, which fact Mr. Jamieson attributes to the presence of more 'available' natural phosphorus in chalk. That phosphatic manures, whether animal or mineral, soluble or insoluble, do not exhaust their effect in the first year, is amply proved by a series of experiments with swedes made at Hasocks Gate, where the difference in the crop on various plots is very marked, according to the dressing applied in the preceding year. The potash experiments plainly indicate the peculiar value of potash as manure on certain soils. One main feature apparent in the results is the injurious effect produced by the chlorine of muriate of potash. For agricultural purposes potassium-chloride has never stood very high in popular estimation. But the ground for this was previously its extreme solubility. Mr. Jamieson taxes it with the exhalation of chlorine, under the influence of which the plants sicken and grow wan and pale. He has remarked—without being able to suggest an explanation—that in soils rich in black vegetable matter—humus—this baneful effect is to a large extent neutralized, as is also the detrimental action of acid already intimated in the case of nitrogenous manures. To arrive at an explanation, he has instituted several ingenious experiments. Among other things, he has dressed a crop of storky swedes, labouring under vegetable 'chlorosis,' with dextrine, with the result of producing a strikingly deep green and healthy colour in the leaves of the plants. The plot gained rapidly on its neighbours. But it did not maintain its superiority. Apart from this interesting result the question under investigation still remains unsolved. Mr. Jamieson recommends the high-priced nitrate of potash in preference to other potash salts. The deficiency-experiments appear to have raised a doubt in Mr. Jamieson's mind whether the leguminous classes of plants (beans, peas, and clover) really deserve the distinctive name of 'potash plants.' Some of these have thriven where potash was designedly withheld. Similar experiments seem to have satisfied Mr. Jamieson that from the familiar heptade of inorganic elements considered to be indispensable for plant life, sulphur and magnesia may in many cases be eliminated, being present only as accidental admixtures. As a useful wheat manure for Sussex, Mr. Jamieson recommends (duly guarding himself against application to every soil)—(1) as autumn dressing—2½ cwt. of sulphate of potash, ½ cwt. of sulphate of lime (or in substitution of both, 1 cwt. of ground kelpite), 3 cwt. ground coprolite flour, ½ cwt. steamed bone flour, and ½ cwt. nitrate of soda; (2) as spring dressing—½ cwt. sulphate of potash, ½ cwt. mineral superphosphate, ½ cwt. steamed bone flour, ½ cwt. nitrate of soda. The mixtures are calculated per acre. As a good root manure Mr. Jamieson recommends 2½ cwt. coprolite flour, ½ cwt. steamed bone flour, ½ cwt. nitrate of soda, ½ cwt. sulphate of ammonia, ½ cwt. horn-dust or dried blood, and 2 cwt. ground kainite.

The experiments will be continued in the present year. The committee have assented to Mr. Jamieson's proposal, according to which the root plots will be cropped with mangolds, without manure, to show the lasting effect of manures already applied; wheat will be grown on the same plots, with 'soil-exhausting' manures; beyond this, some interesting experiments will be made at Hasocks Gate to elucidate the question of mineral ingredients absolutely essential to plant growth.—*Sussex Advertiser.*

NOTES ON POULTRY-KEEPING.

FOOD.

NO doubt, what constitutes the greatest cost in a poultry-yard is the daily food, and we must not be blind to the fact that, if left in the hands of unskilful people, the owner soon finds out the enormous expense to which he has been put, so much so, that we have often heard the remark that after paying high prices for grain, the eggs they receive in return cost them each the same price that would be paid for a dozen, if judiciously managed.

The feeding of poultry is a very simple, but not always an easy, problem. The expense of building fowl-houses and other accessories is known; whether they be costly or insignificant, they represent capital which in time brings forth fruit; but a daily food is a problem which must be solved at every moment, and, if badly solved, it misleads, and the misleading carries you on to losses which increase daily.

There is no living creature of the animal kingdom in respect of feeding that possesses such a multiplicity and variety of taste as the cock and hen. They are granivorous, herbivorous, omnivorous,

vermivorous, and insectivorous; they feed without distinction upon everything that is offered; they refuse nothing. With such a conformity of stomach open to receive substances so diversified, we must admit there is a large margin; moreover, whatever the ingredients, they thrive upon them, they prosper, and the aim of the owner is obtained by getting the most satisfactory result.

But the result can only be obtained by judicious feeding. If fowls are only allowed to eat what they can pick up, it would be a very poor one, unless they have the run of a stockyard at harvest time, when one need not trouble much about them; but in every other season of the year they must be attended to night and morning. Another important point is to know what a hen can eat so as to satisfy her hunger and keep her in good condition; this is a great consideration, which must not be acted upon at a guess, for on the proper quantity depends the whole success of the undertaking; in fact, it is the turning point. If too much food is given, it turns to plethora and manure; the hen under these circumstances becomes almost sterile, and if she does lay it is only at rare intervals. If not fed enough, the hen, not finding sufficient nutriment for her own subsistence, cannot produce either eggs or flesh. The result would be nil in both cases. To obviate this, a medium must be found by which surplus fat is avoided on the one side, and on the other to prevent the loss of flesh necessary for her maintenance as a producer.

A practical farmer in France, Monsieur François Rouillet, the author of a book on poultry, asserts that a hen having liberty to roam about requires 120 grammes (4½ oz.) of corn per diem, and a hen in confinement requires 60 grammes more, or 180 grammes (6½ oz.) On the other hand, Monsieur Mariot Didier, who has published a work in two volumes on the same subject, maintains that with 60 grammes of oats (2½ oz.) a hen of moderate size can be amply fed. The same author even goes further, and says that 45 grammes of buckwheat (1½ oz.) is sufficient to keep a hen in good condition as a producer. There is evidently some error, as there is an enormous difference in the estimation of those two gentlemen, which is far too great for any poultry-keeper to act upon.

To set at rest this question, a Belgian nobleman, a student of natural history in general, and of poultry in particular, has put to the test the remarks made by the above authors, and it is only by experiments on different subjects that this problem of feeding poultry has been solved in a satisfactory manner, as being the master-mover of a profitable poultry-yard. For that purpose, three lots of hens, of ordinary size and of the common sort, were chosen. Each lot, composed of ten hens, was confined during a month in runs about 20 to 22 yards of area. The first lot was exclusively fed on barley, the second on buckwheat, and the third on oats. To each of these three lots 1000 grammes, or 1 kilogramme (about 2½ lbs.), of these different grains were given each day. On making up the three lots, each was put into the scales; the first lot weighed 18 kilos (39½ lbs.), the second 17½ kilos (38½ lbs.), the third 18½ kilos (40½ lbs.). At the end of the month they were again weighed, and the following is the result:—The first 40½ lbs., the second 38½ lbs., and the third 39½ lbs. so that it is pretty certain that the food given was sufficient to keep them in good condition.

We see that oats proved to be less nutritive than the other grain, still the hens were satisfied with the portion they had. We may remark that these hens were confined so that they were obliged to feed exclusively on grain, thereby debarred from picking up any extras; then, taking into consideration what they find when at liberty, we may fairly argue that 75 grammes, or 2½ oz. of grain, are sufficient for each head of poultry daily, being a very liberal allowance.

Having established the quantity required for each fowl, the breeder can easily count his cost on the one hand and his receipts on the other. In case grain is too dear, which may happen, there are other means at times very economical—take, for instance, the potato. This is very suitable to hens when boiled and given to them hot; it assists the laying to a great extent; but bearing in mind the profit the farmer is to derive from his yard, potatoes must be cheap, otherwise he must seek other substitutes.

Beetroot, turnips, carrots, &c., boiled and mixed with bran or middlings, is a very excellent food for fowls; but if fed solely on grain, grass, and vegetables, the hen would drag on her existence, but would be neither a good layer nor a good sitter. A hen requires food of a stimulating nature. As we have said before, she is granivorous, herbivorous, carnivorous, &c.; she eats all these substances; she digests them all, however hard they might be; her digestive organs are so constructed that in her excretions no particles of grain or other substance is seen. She is very fond of meat, which is very easily digested; even particles of bones remain in the stomach until thoroughly digested, and are ejected in the same state as other food.

The hen being carnivorous, flesh or meat is then one of the constituent parts of her food. A farmer can always obtain horse-flesh or inwards of animals at a very moderate rate, which being boiled and cut up, and given in the same quantity as grain, will always keep fowls in the best of order. The hen, as a vermivorous bird, is always seeking after worms and insects, and they have a great affection for larvae and chrysalis, which they seek all day during the whole of the warm weather; but in late autumn, or in winter, when it is difficult to obtain them through their own exertions, farmers ought to assist them by establishing vermiferes, or 'vermination beds,' by which larvae, &c., can be easily produced in large quantities, and which would prove a very great boon to poultry, at a mere nominal price.

In our next chapter we will give a description of a 'vermifere.'

THE NECESSITIES FOR JUMING.

It is now many years since Government, seeing the waste of forest caused by juming, undervalued to put a stop to the practice by pointing out to its officers the desirability of putting some sort of pressure on those who pursued this "wasteful and wasteful custom," as it was called.

Near Darjeeling, Sir Ashley Eden had hopes of producing some effect, by summoning the chiefs of those communities that jumed, and having its desire explained to them.

In vain the chiefs urged the impossibility of confining their people to one plot of ground, but seeing Government determined, they promised to do all they could.

Some two years after, it was officially recognized that the custom was not in the slightest degree abated. The people jumed as before, regardless of the orders. On looking into the matter, it is noteworthy that the custom is extremely old, and evidently preceded the Aryan irruption into India by which the plough was introduced, and that juming despite a few exceptions is in India a race character of the great non-Aryan group. It appears pretty clear that in pre-Aryan times the country was covered by a huge tropical forest, jumed everywhere by the indigenous races called by the Aryans demons.

Thus the custom is actually older than the languages and physique we now see among the non-Aryan hill tribes, who have been driven from the plains, and have since largely differentiated.

Neither the plough nor the hoe are non-Aryan implements, and were they abolished, juming is the only alternative. Human customs are often unaccountably persistent, even after the causes are removed, but to understand juming, let us examine it where the custom is still a necessity, and where indeed it is a far more laborious system of cultivation than by plough or hoe. Taking the Naga hills, as a good example, we generally see tribes, villages, or communities owning and cropping in rotation an area from six to ten times that needed for a year's crop.

The hills around are seen in various stages of forest growth, or grass, where crops have been last taken off. It is also found on enquiry that each family has its land carefully marked out by stones, ridges or gullies, on each of some six or eight different sites, on the hill slopes around, and that are jumed in rotation.

This year's jume may be due east, last year west, and the year before to the south, and so on, a new site being cleared each year, and at first put under root crops, &c., called "No erra," the second year under grain, and called "Hera erra," after which, as a rule, it is thrown up. The various sites are usually, though not invariably, taken in rotation, and when the forest growth is say eight or ten years old. On selection, the men and boys go to it and look up their boundaries, cutting or marking them, and first clear all the undergrowth.

When this is done they fell the trees, leaving and lopping a few where they desire to train their *pan*, *alus*, &c., and cut the rest up so as to lie close, and thus burn thoroughly. After six weeks or so, and when sufficiently dried, it is all fired, giving rise to the huge vertical or columnar clouds with a spreading top so often seen in the hills in spring.

Men, boys, and women then collect the stems, branches, &c., and burn round the stems of any large trees that it may be desirable to kill, or form of the sticks and logs an effectual abatis to keep out animals.

In this newly cleared land they plant yams, *alus*, cotton, *pan*, *kuchus*, chillies, &c., and it is the "No erra." Last year's clearing is also cleared over by the *dao*, the cropper grass and plants cut down, and fired when dry, and in this they dibble the hill paddy, it is the "Hera erra."

As the season advances both sites must be weeded as grass springs up, and as may be supposed the rice gives some trouble being so like grass; a little loop of bamboo, or an iron hoe the size of a table spoon is used in weeding.

The hill paddy is usually weeded three times, and on the hill *aldas* may be seen, here a long line of women and girls, on another slope the men and boys, 10, 20 or 30 in a line, and the work is communitative. Thus one plot of ground gives, the first year root crops, &c.; the second year, hill rice, and is seldom planted the third year, as grasses come up so thickly, especially *ulu* (*Imperata cylindrica*), that rooting and growing underground defies entirely their limited agricultural implement, the *dao*.

In the fourth year, the site is generally dense *ulu*, through which one can only get by paths or on an elephant; here and there tree plants are up, also the larger grasses, as *mol*, *kagra*, *megolla* (*Saccharum spontaneum*), rising to 20 and 25 feet, (*megolla* has measured 33.) creepers also appear, and some creeping grasses that rise over the *ulu*.

In the fifth year tree plants predominate, as there are no jungle fires known in these hills, and at last all trace of the *ulu* has disappeared by the seventh or eighth year, and the site is ready again.

Fire does not kill *ulu*, water and shade are the means most effectual, and hoeing, as a rule, on such slopes is worse than the disease, and the soil at times too stony. The roots or rather rhizome is often a foot deep.

The grasses of Eastern Bengal and Assam are about 170 kinds, and may be roughly grouped by their modes of propagation.

THICK HEADS,

Heavy stomachs, bilious conditions—Wells' May Apple Pills—anti-bilious, cathartic. As. 4, p. 1, and As. 10. B. S. Madon & Co., Bombay, General Agents for India.

* The name is Naga, from Nok, and not Naga.

Forest grasses, the seeds of which are at a height to touch animals passing, and having spines, hooks, or gum as modes of attachment (when ripe).

Those of the open uncultivated plains, where the wind transports them, the minute seed being on a high kalm, and covered by down.

Again, seeds of grasses, that are like grain, and are transported by birds, others with light husks by *u-ber*. *U-ber* has a minute seed on a kalm and fine down attached; which enables it to travel long distances, and when once rooted, another and unique mode of propagation at once comes into play, by its rapidly spreading underground, among stones and roots, or even to a depth of a foot and 18 inches in clay. It is this peculiarity of a grass, the seeds of which fill the air in myriads and travel immense distances, that lies at the root of the necessity for juming, among most hill tribes to the south and east of Assam, and also the north, where neither hoeing nor ploughing is possible.

Hill soils are proverbially rich, and exhausted soil is certainly not the cause, as we have cases in the adjoining plains where rice has been cropped for 200 years without intermission, or manure. The cure for juming is to introduce some other crop like potatoes and plantains, where a much smaller area will support the same people, where the labour of cultivation can be concentrated.

It is highly probable that juming survives in places where there is less need for it than formerly. But to suppress it by law, as a "barbarous system," would entail the necessity of our supporting all the hill people around Assam.

There is generally a good cause for everything; the above is one cause for the necessity of juming.

—Indian Forester.]

S. E. PRAL.

Note.—Since writing the above, I see at page 94, Proceedings of the Royal Geographic Society—

"The Tinbunwahs of Borneo live a peaceful rural life, and have no very particular points of interest about them: it is their custom to move from one place to another on the banks of the river, building a very slight house, clearing the ground, and planting, in an idle sort of way, paddy, bananas, Indian corn, sweet potatoes, and the like. Grass sooner or later makes its appearance; very slight attempts are made to keep it down. After a time (generally about three years from clearing) it has gained the upper hand, and the stumpy house about this time usually collapses, and a move is made for a fresh location."

WOBURN CROP EXPERIMENTS.

A LARGE gathering of agriculturists assembled at Woburn the other day, by invitation of the Council of the Royal Agricultural Society, to make the annual inspection of the field experiments which are being conducted on a farm set apart for the purpose by the Duke of Bedford. General approval was expressed to the manner in which the cultivation and management of the crops and the preparation of the farmyard manure are being carried on, and the present appearance of the numerous plots displays a satisfactory growth, the differences in luxuriance and vigour of the variously manured wheats and barleys amply confirming to the eye the evidence reported of the almost invariable results during several harvests from each order of manurial treatment adopted.

The primary object was to ascertain by practical trials made under conditions of scientific exactness, what are the relative values of manure obtained from the consumption of different articles of food by animals. Accordingly, the farmyard manure used is prepared in three different ways—one portion by giving the cattle decorticated cotton-cake, which is very rich in nitrogenous constituents, and is, therefore, estimated to yield a manure of high value; another portion by giving maize-meal, which is estimated to yield a manure of low value; and a third portion is prepared without any such purchased food, all the lots of cattle being fed with similar quantities of roots, chaff, and straw. For the purpose of comparing the effects of the food-prepared manure with those of artificial manure, parts of the crops are dressed with nitrogen, potash, phosphoric acid, and other chemicals, equivalent to the constituents contained in the cotton-cake and maize-meal respectively. The rotation known as the four-course shift is followed upon an area of 16 acres. Four acres of mangolds or swedes are grown with four different manurings—namely, one acre with cake-dung, one acre with maize-dung, one acre without dung from purchased food, but with artificial manure corresponding to the cake manure, and one acre also without dung from purchased food, but with artificial manure corresponding to the maize manure. There are four acres of barley following the mangolds, there are four acres of seeds following the barley, and four acres of wheat following the seeds. The seeds are fed off by sheep, part supplied with cotton-cake, part supplied with maize-meal, and part receiving no food but the herbage, and the increase in live weight in each case is noted. The value of taking a fourth part of the land under each crop, instead of the whole under roots one year, barley the next, all seeds the next, and all in wheat in the fourth year, is that a fairer average of results can be arrived at when all the experiments are made in every season as a year favourable to one of the kinds of manurial treatment might chance to be unfavourable to another.

WELLS' "ROUGH ON CORNS."

Ask for Wells' "Rough on Corns." As. 6, p. 1. Quick relief, complete, permanent cure. Corns, warts, bunions. B. S. Madon & Co., Bombay, General Agents.

The following table shows the general results of six years' experiments with the roots:—

WEIGHT OF ROOTS.

| In the year. | Acre manured from roots, chaff, straw, and 1000 lbs. cotton-cake. | Acre manured from roots, chaff, straw, and 1000 lbs. maize-meal. | Acre manured from roots, chaff, straw, and artificial manures equivalent to cotton-cake. | Acre manured from roots, chaff, straw, and artificial manures equivalent to maize-meal. |
|--------------|---|--|--|---|
| | Tons. Cwt. | Tons. Cwt. | Tons. Cwt. | Tons. Cwt. |
| 1877 ... | 3 17 | 2 1 | 7 4 | 3 16 |
| 1878 ... | 13 2 | 11 16 | 18 13 | 12 15 |
| 1879 ... | 4 10 | 4 9 | 7 19 | 5 15 |
| 1880 ... | 19 10 | 18 19 | 24 10 | 20 18 |
| 1881 ... | 22 5 | 21 14 | 24 7 | 21 13 |
| 1882 ... | 17 6 | 17 1 | 19 13 | 18 3 |
| Average ... | 13 8 | 12 13 | 17 1 | 13 16 |

The average of six years' experiments comes out somewhat in favour of cotton-cake dung over maize-meal dung; but the estimate of agricultural chemists that the manurial residue left from feeding cotton-cake greatly exceeds that from maize-meal is not borne out at all. In fact, in the last two years the results from both were very nearly identical. Artificialists reckoned as equivalent to the actual *residuum* from the food are more effective than chemical calculation allows for.

For five years' trial of barley on the same acres in each year following the roots, the results, as far as bushel measures are concerned, appear thus:—

PRODUCE OF BARLEY AFTER ROOTS.

| In the Year. | Acre after roots from cotton-cake manure. | Acre after roots from maize-meal manure. | Acre after roots from artificials equal to cotton-cake manure—the barley top-dressed with artificials. | Acre after roots from artificials equal to maize-meal manure. |
|--------------|---|--|--|---|
| | Bushels. | Bushels. | Bushels. | Bushels. |
| 1878 ... | 41.3 | 38.8 | 51.4 | 36.4 |
| 1879 ... | 38.0 | 40.6 | 45.7 | 32.8 |
| 1880 ... | 41.3 | 37.0 | 41.0 | 33.4 |
| 1881 ... | 50.6 | 47.3 | 51.0 | 51.0 |
| 1882 ... | 51.3 | 48.1 | 46.6 | 46.3 |
| Average ... | 44.5 | 42.7 | 47.1 | 40.0 |

The cotton-cake manure plots gave an average of 44½ bushels, against 42½ bushels from the maize-meal manure plots. The yield from the artificial manure plots was still greater, where the constituents equivalent to cotton-cake manure, and also an extra dose of artificial were applied, but considerably smaller where only constituents equivalent to maize meal manure were applied.

After barley come seeds, each acre fed off by ten sheep—one lot supplied with cotton-cake, one with the same weight of maize-meal, and the sheep on the remaining two acres receiving no other food than the herbage. The average increase in live weight of the several lots of sheep, as repeated for six seasons, appears as follows:—

INCREASE IN LIVE WEIGHT OF SHEEP GRAZING SEEDS AFTER BARLEY.

| In the Year. | Increase in live weight of 10 sheep on one acre of seeds, having 728 lbs. of cotton-cake. | Increase in live weight of 10 sheep on one acre of seeds, having 728 lbs. of maize-meal. | Increase in live weight of 10 sheep on one acre of seeds, without other food. | Increase in live weight of 10 sheep on one acre of seeds, without other food. |
|--------------|---|--|---|---|
| | Lbs. | Lbs. | Lbs. | Lbs. |
| 1877 ... | 303 | 275 | 214 | 210 |
| 1878 ... | 447 | 444 | 392 | 326 |
| 1879 ... | 328 | 435 | 314 | 280 |
| 1880 ... | 262 | 317 | 220 | 314 |
| 1881 ... | 434 | 352 | 134 | 168 |
| 1882 ... | 345 | 402 | 199 | 116 |
| Average ... | 363 | 371 | 245 | 231 |

Here the cotton-cake feeding did not tell so well as the feeding on an equal quantity of maize-meal; and in both cases, of course,

the increase in live weight was very much less when the animals got no artificial food. The object, however, was to try the effect upon the subsequent wheat crop. The average results for five years, so far as bushels of dressed corn are concerned, are these:—

PRODUCE OF WHEAT AFTER SEEDS.

| In the Year. | Acre after seeds fed off by sheep, with 728 lbs. cotton-cake. | Acre after seeds fed off by sheep, with 728 lbs. maize-meal. | Acre after seeds fed off by sheep, without cake or corn—the wheat top-dressed with artificial manure equivalent to cotton-cake. | Acre after seeds fed off by sheep, without cake or corn—the wheat top-dressed with artificial manure equivalent to maize-meal. |
|--------------|---|--|---|--|
| | Bushels. | Bushels. | Bushels. | Bushels. |
| 1878 ... | 41.3 | 43.6 | 56.8 | 39.4 |
| 1879 ... | 39.8 | 40.7 | 42.7 | 41.7 |
| 1880 ... | 22.7 | 26.2 | 21.9 | 25.1 |
| 1881 ... | 56.4 | 57.4 | 58.9 | 55.3 |
| 1882 ... | 42.8 | 43.3 | 42.1 | 46.1 |
| Average ... | 40.5 | 42.1 | 43.3 | 41.5 |

The influence of season appears more powerful than the manurial treatment, as fairly uniform differences occurred in the yield between one harvest and another. The averages show a better result from the residual manure of the maize-feeding than from the residual manure of the cotton-cake feeding—a demonstration completely opposed to the teaching of the agricultural chemists, as founded upon analyses of feeding stuffs.

STERILITY OF ANIMALS IN CONFINEMENT.

AN interesting department of the sterility of animals is that which results from confinement. This seems specially to affect what are vaguely designated the noble animals. Those which are sterile show great variations; some disdain to cohabit or have lost sexual desire; others have increase of sexual appetite, and cohabit freely or excessively, but without impregnation resulting, or with the result very rarely following. Some, if impregnated, bring forth only abortions, or young which are dead-born, or, if alive, feeble and ill-formed. There is, for instance, as Shorthouse has pointed out, a common occurrence of cloot palate in the lion's cubs born in the Zoological Gardens.

Among birds in confinement there are many good examples of change of sexual habits and of sterility. In some cases they have no eggs, or, if they produce, they have only comparatively few, or they may neglect the eggs when produced, or the eggs duly cared for may be incapable of being hatched. This abortive sterility, arising from imperfection of eggs as a result of confinement, is well proved by experiments made in France on the common fowl. When these birds were allowed considerable freedom, 20 per cent of the eggs failed to be hatched; when less freedom was allowed, 40 per cent failed; when closely confined, 60 per cent were not hatched.

The power of temperatures that are not according to an animal's nature to induce sterility is no doubt very great. Darwin mentions that Mr. Millor, a former superintendent of the Zoological Gardens, believes that the sterility of the carnivora there was increased by increase of exposure to air and cold. In winter inadequately sheltered cows either ceased to give milk or gave it in diminished quantity. "And" says Spencer, "though giving milk is not the same thing as bearing a young one, yet, as milk is part of the material from which a young one is built up, it is part of the outlay for reproductive purposes, and diminution of it is a loss of reproductive power." Failure to maintain the cow's heat may entail such reduction in the supply of milk as to cause the death of the calf. Hard living, says Darwin, retards the period at which animals conceive, for it has been found disadvantageous in the northern Highlands of Scotland to allow cows to bear calves before they are four years old. Roulin found that in the hot valleys of the Equatorial Cordilleras sheep were not fully fecund.

The common fowl will not breed in Greenland or Northern Siberia. "In this country, it is fed," says Spencer, "through the cold months, but, nevertheless, in midwinter it either wholly leaves off laying or lays very sparingly. And then we have the further evidence that if it lays sparingly, it does so only on condition that the heat, as well as the food, is artificially maintained. Hens lay in cold weather only when they are kept warm, to which fact may be added the kindred one, that when pigeons receive artificial heat, they not only continue to hatch longer in autumn, but will recommence in spring sooner than they would otherwise do."

On the subject of the interbreeding of animals, there is a vast body of opinion as well as of facts showing its power in producing monstrosity and its ally, sterility. "If we were," says Darwin, "to pair brothers and sisters in the case of any pure animal, which from any cause had the least tendency to sterility, the breed would assuredly be lost in a few generations." Elsewhere he shows that "long-continued close interbreeding between the nearest relations diminishes the constitutional vigour, also, and

fertility of the offspring, and occasionally leads to malformations, but not necessarily to general deterioration of form or structure. This failure of fertility shows that the evil results of interbreeding are independent of the augmentation of morbid tendencies common to both parents, though this augmentation no doubt is often highly injurious. Our belief that evil follows from close interbreeding rests, to a large extent, on the experience of practical breeders, especially of those who have seen many animals of the kind which can be propagated quickly; but it likewise rests on several carefully recorded experiments. With some animals close interbreeding may be carried on for a long period with impunity by the selection of the most vigorous and healthy individuals; but, sooner or later, evil follows. The evil, however, comes on so slowly and gradually that it easily escapes observation, but can be recognised by the almost instantaneous manner in which size, constitutional vigour, and fertility are regained when animals that have long been inbred are crossed with a distinct family."

Regarding the very remarkable subject of sterility of sexual connection with special individuals only, Darwin says:—"It is by no means rare to find certain males and females which will not breed together, though both are known to be perfectly fertile with other males and females. We have no reason to suppose that this is caused by these animals having been subjected to any change in their habits of life. . . . The cause apparently lies in an innate sexual incompatibility of the pair which are matched. Several instances have been communicated to me by Mr. W. C. Spooner (well known for his essay on cross-breeding), by Mr. Eytton, by Mr. Wicketed, and other breeders, and especially by Mr. Waring of Chislefield, in relation to horses, cattle, pigs, fox-hounds, other dogs, and pigeons. In these cases, females which either previously or subsequently were proved to be fertile, failed to breed with certain males with whom it was particularly desired to match them. A change in the constitution of the female may sometimes have occurred before she was put to the second male, but in other cases the explanation is hardly tenable, for a female known not to be barren has been successfully paired seven or eight times with the same male likewise known to be perfectly fertile. With cart-mares, which sometimes will not breed with stallions of pure blood, but subsequently have bred with cart stallions, Mr. Spooner is inclined to attribute the failure to the lesser sexual power of the race-horse. But I have heard from the greatest breeder of race horses at the present day, through Mr. Waring, that it frequently occurs with the mare to be put several times during one or two seasons to a particular stallion, of acknowledged power, and yet prove barren, the mare afterwards breeding at once with some other horse. These facts are worth recording, as they show, like so many previous facts, on what slight constitutional differences the fertility of an animal often depends."

Before leaving the subject of the causes of sterility of animals, I quote a passage from Darwin regarding the results of confinement: "Sufficient evidence," says he "has now been advanced to prove that animals, when first confined, are eminently liable to suffer in their reproductive system. We feel at first naturally inclined to attribute the result to loss of health, or at least to loss of vigour; but this view can hardly be admitted when we reflect how healthy, long-lived, and vigorous many animals are under captivity, such as parrots, and hawks when used for hawking, cheetahs when used for hunting, and elephants. The reproductive organs themselves are not diseased, and the diseases from which animals in menageries usually perish are not those which in any way affect their fertility. No domestic animal is more subject to disease than the sheep, yet it is remarkably prolific. The failure of animals to breed under confinement has been sometimes attributed exclusively to a failure in their sexual instinct; this may occasionally come into play, but there is no obvious reason why this instinct should be specially liable to be affected with perfectly tamed animals, except, indeed, indirectly, through the reproductive system itself being disturbed. Moreover, numerous cases have been given of various animals which couple freely under confinement, but never conceive, or, if they conceive and produce young, these are fewer in number than is natural to the species. In the vegetable kingdom instinct of course can play no part, and we shall presently see (he says) that plants, when removed from natural conditions, are affected in nearly the same manner as animals. Change of climate cannot be the cause of the loss of fertility, for, whilst many animals imported into Kiaropo from extremely different climates breed freely, many others when confined in their native land are completely sterile. Change of food cannot be the chief cause, for ostriches, ducks, and many other animals, which must have undergone a great change in this respect, breed freely. Carnivorous birds, when confined, are extremely sterile, whilst most carnivorous animals, except plentigrades, are moderately fertile. Nor can the amount of food be the cause, for a sufficient supply will certainly be given to valuable animals, and there is no reason to suppose that much more food would be given to them than to our choice domestic productions which retain their full fertility. Lastly, we may infer from the case of the elephant, cheetah, various hawks, and of many animals which are allowed to lead an almost free life in their native land, that want of exercise is not the sole cause. It would appear that any change in the habits of life, whatever those habits may be, if great enough, tends to affect, in an inexplicable manner, the powers of reproduction. The result depends more on the constitution of the species than on the nature of the change; for certain whole groups are affected more than others; but exceptions always occur, for some species in the most fertile groups refuse to breed, and some in the most sterile groups breed freely. Those animals which usually breed freely under confinement rarely breed, as I was assured, in the Zoological Gardens, within a year or two after their first importation. When an animal which is generally sterile under confinement happens to breed, the young apparently do not inherit this power; for had this been the case, various quadrupeds and birds which are valuable for exhibition

would have become common. Dr. Broca even affirms that many animals in the Jardin des Plantes, after having produced young for three or four successive generations, become sterile; but this may be the result of too close interbreeding. It is a remarkable circumstance that many mammals and birds have produced hybrids under confinement quite as readily as, or even more readily than, they have procreated their own kind. Of this fact many instances have been given, and we are thus reminded of those plants which, when cultivated, refuse to be fertilised by their own pollen, but can easily be fertilized by that of a distinct species. Finally, we must conclude, limited as the conclusion is, that changed conditions of life have an especial power of acting injuriously on the reproductive system. The whole case is quite peculiar, for those organs, though not diseased, are thus rendered incapable of performing their proper functions, or perform them imperfectly."—*Extract from the Galtonian Lectures, delivered by J. Matthews Duncan, M.D., F.R.C.P., L.*

GRAZING RIGHTS IN FORESTS.

IN the letters which have recently appeared in the *Forester*, the effect of grazing on the forest vegetation has alone been discussed; and it has apparently been assumed that, provided it was shown that grazing was not immediately and directly injurious to the reproduction, no further objection could be made against it.

While, however, fully admitting that this is the most important point that we have to consider in connection with grazing, I am of opinion that the probable effects of grazing rights on general forest management deserve attention in a discussion on the policy of excluding grazing from a certain class of forests.

Apart from cultural considerations, I think that the existence of such rights would weaken our control over the forests, and that they would be, in general, an element of insecurity in our protective measures. All forest rights tend to become more onerous, and it is difficult, even where carefully prepared records exist, to prevent the demand the right supplies from gradually increasing during a long series of years with the general growth of the population. Moreover forest grazing has this peculiarity about it that, within limits of course, the more a forest is grazed over, the more pasturage will be found on it. The patches of short cropped grass increase in extent, and, as the cover lightens (as lighten it must in time in any forest where the grazing is constant and severe, but I will allude to this later on) spread over the entire area.

The history of forestry in all European countries furnishes us with numerous examples of the growth of rights, which, when granted, must have appeared harmless enough. In the *Forester* for April last, we find, as an instance of this, some interesting facts regarding the extinction of rights in Epping Forest:—

"The extinction of rights of fuel in the Manor of Waltham, Holy Cross and Sewardstone, which were utterly destructive to the appearance of the forest cost £15,000, and £7,000 were paid to the inhabitants of Longton to extinguish their rights of lopping. The entire cost of the arbitration cost £109,505."

In European countries, where the indirect evils from grazing are less injurious than in India, it has been admitted without question, not alone by professional foresters, but by the general public, that grazing rights are a serious danger to the State forests, and large sums of the public money have been devoted to the extinction of these rights. A recent writer in the *Revue des Eaux et Forêts* thus expresses this opinion:—

"L'Extinction des droits de pâturage dont les forêts domaniales sont encore grevées est de la plus grande importance, non seulement au point de vue de l'intérêt du Trésor, mais surtout au point de vue de l'intérêt social. Personne ne conteste en effet, que les droits de pâturage, quand ils ne sont pas une cause de détérioration progressive, de ruine finale pour les forêts, sont du moins toujours un obstacle à leur amélioration."

In the peculiar conditions under which forest work is carried on in India, these objections to grazing, in any forest whatever, irrespective of the direct injury done to the vegetation, appear to me so weighty and important, that I think it would be impolitic to allow grazing rights of any sort, even in deodar forests, whenever this can be avoided.

But at the same time I agree with Mr. Moir in protesting against forests being left unreserved, simply because we cannot entirely exclude grazing from them, while I believe that grazing alone, when sufficiently severe and constant, can, in time, cause the annihilation of ANY forest, even deodar. I am convinced that with proper restrictions, and by closing, if necessary, parts of the forest for a time, any forest can be at least preserved, in spite of grazing; but that a right of grazing from its tendency to increase, is always a serious danger, and should be avoided where possible. The fact that forests can exist and reproduce themselves in spite of moderate grazing, is proved by our finding forests still in India, just as conclusively as the fact that large forest areas have disappeared under the united influence of over-felling and grazing, proves the necessity for State interference in forest management.

But until the time, certainly not yet within a measurable distance, when the natives of this country more generally grow fodder crops, immense areas must continue to be devoted to grazing. Many of these areas, which as a rule are unfit for cultivation, are still fairly well stocked with timber, and could be improved and continue to furnish both timber and pasture under a simple system of forest management; and there are many cases in which, owing to peculiar circumstances, such as the feeling of the people, or the opposition of the Civil authorities, it is practically necessary to accept forests burdened with grazing rights.

But this is no reason why we should allow forests to be burdened with rights, when this can be avoided, under the mistaken notion

that they will not be an obstacle to improvement. *Apropos* of the discussion on the effect of grazing in deodar forests, some facts relating to the "ohir" (*pinus longifolia*) forests in the Murree Hills may be of interest.

In many parts of these forests, where fires have not recently occurred, we find, in spite of grazing which has never been prohibited or in any way restricted, a dense crop of vigorous young seedlings, and these do not appear to have suffered in any way. Where, however, the cover of the forest has been removed by felling or lopping, so as to allow an unbroken stretch of grass to spring up, there are as a rule no seedlings. In several places the forest land has been cleared for cultivation and then abandoned. In sequestered places far away from villages, the forest has sprung up again on these cleared places, but where grazing has been more severe, this has not happened, and the cleared places remain perfectly bare. Now, as I have already stated, seedlings of any size do not appear to be injured by grazing, but it would appear that when they come up in short grass they are constantly browsed down while still very young. For it is impossible to suppose that none germinated in the bare places, when we find similar cleared places well stocked with seedlings. Darwin gives an example of this in his *Origin of Species*.

"But how important an element enclosure is I plainly saw near Farnham in Surrey. Here there are extensive heaths with a few clumps of old Scotch fir on the distant hilltops! Within the last ten years large spaces have been enclosed, and self-sown firs are now springing up in multitudes so close together that all cannot live. When I ascertained that these young trees had not been sown or planted, I was so much surprised at their numbers, that I went to several points of view whence I could examine hundreds of acres of the unenclosed heath, and literally I could not see a single Scotch fir, except the old planted clumps. But on looking closely between the stems of the heath I found a multitude of seedlings and little trees which had been perpetually browsed down by cattle. In one square yard, at a point some hundred yards distant from one of the old clumps, I counted thirty-two little trees; and one of them with twenty-six rings of growth, had during many years tried to raise its head above the stems of the heath, and had failed. No wonder that as soon as the land was enclosed, it became thickly clothed with vigorously growing young firs."

I cannot believe that this does not take place in deodar forests also, and it would appear to be a mistake to suppose that animals grazing do not injure the young seedlings of species such as deodar and other conifers that, when older, they will not touch. In fact it would appear certain that where the grazing is sufficiently severe and constant, every seedling is eaten down as soon as it appears, and reproduction becomes absolutely impossible.

Of course, where the number of animals pastured is small compared with the area, this could not happen; and if in addition to this the land is hilly and uneven or rocky, the majority of the seedlings of unpalatable species, many of which would come up out of the little tracks followed by the animals when grazing or between rocks, would entirely escape injury from such limited grazing. We may indeed go further and suppose that where there was a struggle between a number of species, those that were unpalatable to the animals would be benefited by grazing under the conditions I have described.

It is, I think, this immense difference between under-grazing and over-grazing, between the injury done by a few animals picking and choosing their food among the undergrowth and patches of grass under the more or less complete cover of a forest, and the injury done by a crowd of animals constantly grazing on a continuous stretch of grass and probably, involuntarily, cropping down every seedling, not absolutely poisonous or nauseous, that accounts for the fact that while we have examples of hill forests disappearing in a few years almost entirely through grazing, we also find cases like those cited by Mr. Moir, or some of the pine forests I have mentioned near Murree, in which, in spite of grazing, reproduction goes on as vigorously as could be desired. The importance of this difference between the effect of light grazing and severe grazing is evident. As the wants the forests satisfy increase with the natural growth of the population, a harmless grazing right may, in the course of time, overwhelm the forest burdened with it.

That the supply of pasture in a forest tends to increase with the demand, I think will be evident to any one who examines a forest constantly grazed over, and who observes the change from soil and undergrowth of the least frequented or denser portions to the hard bare soil patches of short grass and, eventually, in the most frequented portions to the continuous stretches of short grass with occasional isolated trees.

With regard to Mr. Moir's very practical argument in favor of limited grazing in deodar forests, namely, that those forests in which grazing is not prohibited are in a very much better condition, as regards reproduction, than those protected from grazing, there is nothing contrary to reason or experience in supposing that the deodar seedlings are benefited where the cattle eat the grass and leave them untouched. But from what I have quoted, it would appear that if the grazing had been a little more severe and constant, this would not have happened, and the seedlings would have disappeared with the grass while still very young, and as grazing tends to increase, it is a wise policy to exclude grazing even where at first not injurious. But I am of the opinion of "Sw." (vide the *Forester* for March) that there is room to doubt that grazing alone was the cause of that superiority noticed by Mr. Moir in the forests grazed over as compared with those on which grazing had been prohibited. Very probably Mr. Moir is correct in his deduction, but he has not offered sufficient facts to place it beyond doubt, that grazing alone and nothing else caused the superiority.

Not long ago I heard a similar fact made use of to prove that fires were beneficial to pine forests,* and that consequently our teaching was nonsense. Since the last ten or twelve years the villagers have been prohibited from setting fire to the pine forests in the hills about Murree, which previous to that time they had regularly burned for pasturage every year. Many of these forests are now, indisputably, in a worse condition than they were some years ago. In fact in some places there are no seedlings at all, and as notwithstanding this the mature trees are being felled, these forests offer a perfect example of the conversion of pine forests into pure grass lands. But this deterioration is not due to the teaching of forestry as regards the injurious effect of fires being erroneous, but to the fact that fires have occasionally broken out, and having the accumulations of several years to feed them, instead of only one, or part of one, as they had formerly, have been much more violent and done much more damage than they did in former years, the seedlings being utterly destroyed instead of only scorched. It may be said that it does not much matter whether the theory or the practice was wrong, the result of forest work in this case is to render the last state of these forests worse than the first. But the failure is due to the common sense rules which experience has taught to be necessary in fire protective measures not being complied with. In fact the forests were made over to the Forest Department saddled with the impossible condition, as far as their protection and improvement are concerned, that the villagers could, with the consent of the civil authorities, extend their cultivation where they liked in them, and fell trees where they liked,† so that it has been impossible either to demarcate or fire-trace these forests.

It may not be out of place to recall here that not very many years ago it was argued that fires were beneficial to teak forests and assisted reproduction, and that by keeping out fires we were adopting a "wrong system."

The late Captain Forsyth, in "The Highlands of Central India," writes as follows:—

"The grass burning universal in these forests" (teak forests of the Satpura Range) "is undoubtedly beneficial in a great variety of ways."

"It has been held by some that these fires are very injurious to the growth of teak saplings and other valuable trees, but it is an undoubted fact that teak seeds will germinate and produce better seedlings where the grass has been fired than where it has not; and it is not well established that much permanent injury is afterwards done to the seedlings. By great efforts fires were kept out of one or two favourably situated teak forests for some years, but no result of consequence to the young trees was observed."

The discussion, however, can never assume much practical value, since it would be quite impossible, with any means at our command, to keep fires out of any but a few very limited and favourably situated localities."

Since this was written hundreds of thousands of acres of teak forests have been annually protected in the Melghat with indisputably a good effect to the forests, and the villagers themselves, the wild Gonds and Kukurs, recognise the wisdom of fire protection.

W. E. D'ARCY.

—The Indian Forester.]

EUCALYPTUS TREE IN THE ARGENTINE REPUBLIC.

CONSUL BAKER, of Buenos Ayres, says that the *Eucalyptus*, styled by some the "fever-destroying tree," is considered to be a very healthful tree, and the pungency of its leaves is such that it is never molested by insects; it is reported to be the only tree grown in the Argentine Republic which the locusts will not attack. It has the reputation of being an effectual destroyer or absorbent of malaria. In Australia, it is said, there are no marsh fevers where large forests of the *Eucalyptus* exist, and the trees have been planted in the Pontine marshes near the city of Rome, with excellent effect. In Buenos Ayres they bruise the leaves, and bind them to the forehead for nervous headache. The leaves themselves are a special abhorrence of such insects as prey upon fruits and fruit trees, against whose visitations they furnish protection by being scattered thickly on the ground underneath. Consul Baker is strongly in favour of introducing this tree into the majority of the European countries, and into the United States, and calls attention to the success which has attended its cultivation in certain districts of France, Italy, Spain, and Portugal. The tree has been planted on a large scale and with good results in Algiers, and at the Universal Exposition of 1867, in Paris, the trunk of a tree only eight years old, having a circumference of between five and six feet, was exhibited. The *Eucalyptus globulus* grows with a rapidity which is surprising. The first year of its planting, its usual growth is about 18 inches per month, when it is planted under favourable circumstances. Its increase in height is somewhat retarded during the second year, but the diameter of the trunk increases, and its branches begin to spread. Owing to this rapidity of growth, forests of these trees are obtained in ten years, which with other trees it would take a century to form. As an example of their increase, it may be stated that in Hyeres, seeds

* But the peculiar conditions under which these forests were made over to the Forest Department, the Forest Officer in charge cannot prevent this destruction, as the villagers can, under orders from the *behindar*, fell any trees they require for their own use.

† These forests are now being demarcated; as soon as this is accomplished, it will be possible to protect them properly.

planted in 1857 had, in 1865, reached the height of 58 feet. In Toulon, the plants grew to 24 feet in two years. In 1868, there were trees in Algiers of three years' growth, which had attained a height of from 30 to 35 feet, and generally in that country they grow at the rate of about 10 feet each season. In Australia, its native soil, trees of fifty years' growth attain an altitude of from 225 to 290 feet, and a circumference of from 50 to 60 feet, producing colossal boards or slabs 160 feet long and 12 feet wide. In the Argentine Republic, the tree has a perfectly straight trunk, and in the forests the branches rarely begin below 60 or 70 feet. The outside bark is loose and shaggy, like the plane tree. When young, the trunk is full of small branches, filled with bluish green leaves. In the first years of its growth the leaves are opposite and sessile, but as the tree assumes its true character they become petiolate and alternate, and their colour changes to a much darker hue, hanging vertically, and presenting their edges to the sun. Their two surfaces are exactly alike; the flowers are white, and produce a capsule-seed vessel of the size of a filbert, which is full of small black seeds similar to those of the onion. The tree will not grow from cuttings: it must be produced from the seed. These are generally planted in boxes, and afterwards transferred to small beds. Two or three seeds are generally planted together, and lightly covered with fine earth or river sand, and afterwards finely-cut straw is strowed over the top, as much to protect them from the hot sun as from heavy rains. In very dry seasons the small plants are watered every fifteen days, but this is not absolutely necessary. The tree requires a deep soil and permeable, neither too light nor too compact, and it does not grow to advantage when there is too much humidity in the earth. The usual time for planting the seed is in the months of February and March. The seeds begin to sprout in eight or ten days. The cultivation of the *Eucalyptus* in the Argentine Republic has only two difficulties to encounter, the first being the irregularity of the seasons. A hard frost out of season, which sometimes occurs, may destroy a large number of plants. It is, however, very rarely that trees that have safely passed the first winter will afterwards be killed by frost. Although the tender shoots may suffer, the tree, for that reason, does not die, but with the first favourable weather new and stronger shoots will spring up. After having changed their leaves, the trees appear to be able to endure greater cold. The other difficulty with which they have to contend is the wind. On account of their rapid growth, the trees become top-heavy with their weight of leaves; and the roots for sustaining such an enormous pressure as a high wind produces are relatively small, so that a south-west *pompero*, especially after a rain-storm, will sometimes uproot whole plantations, and this is particularly likely to happen during the second year of their growth. To provide against this, planters in Buenos Ayres make use of stakes and supports to guard against the danger to which the trees are exposed. When the trees are placed close together, they assist to protect each other, and when they are planted under the lee of a belt of timber, which is frequently done, they are better enabled to resist the wind. After the third year they are thinned, and those thus cut away are used as stakes or guards for the rest.—*Journal of the Society of Arts*.

CINCHONA.

THE following is the resolution on the Annual Report of the Government Cinchona Plantation in Bengal for the year 1882-83, and the Annual Report of the Quinologist for the same year:—

The result of the planting operations of the year shows a decrease of about 50,000 cinchona trees on the returns of 1881-82. This is due to the uprooting of a large number of the *Calisaya* and hybrid varieties which were found to possess bark of poor quality. Some 180,000 red bark trees were also uprooted in the ordinary rotation, and were replaced by the yellow bark and hybrid varieties. Nearly all the land within the existing cinchona reserve suitable for the cultivation has now been planted out, and the Superintendent accordingly applied, in October last, for permission to plant out with *Ledgeriana* and the hybrid variety a tract of land in the trans-Teesta portion of Darjeeling which had been reserved for Government cinchona cultivation. Both these species have been proved by repeated analyses to be very rich in quinine, while most of the yellow bark or quinine-yielding trees on the existing plantations at Mungpoo are quite young, and the whole stock is not sufficient to furnish, even when mature, enough bark to employ the factory profitably for more than a few weeks in the year. There is in fact no plantation of these trees actually in existence, while the nurseries have a magnificent stock of nearly half-a-million plants of the best sorts of yellow bark trees which would be lost unless the seedlings were speedily planted out. The proposal for forming the new plantation was readily approved by Government, and measures have since been taken for planting out the reserve with a number of the best kinds of *Ledgeriana* and hybrid cinchona.

2. In the Resolution recorded upon the proceedings of last year, it was remarked that there were several distinct forms of the hybrid variety, and analyses were given of the samples of bark of four of these forms. During the year under review the Superintendent had analyses made of four more of these forms, and

the results obtained from all the eight hybrids are compared in the following tables:—

| | No. 1. | No. 2. | No. 3. | No. 4. |
|---------------------------------------|---------|---------|---------|---------|
| Crystallised sulphate of quinine | 2.87 | 1.48 | 1.88 | 0.97 |
| Crystallised sulphate of cinchonidine | 2.94 | 2.85 | 2.93 | 1.94 |
| Crystallised sulphate of quindine | traces. | traces. | traces. | traces. |
| Cinchonine (alkaloid) | 0.72 | 0.57 | 0.52 | 0.80 |

| | No. 5. | No. 6. | No. 7. | No. 8. |
|---------------------------------------|---------|---------|---------|---------|
| Crystallised sulphate of quinine | 2.12 | 2.04 | 6.12 | 3.90 |
| Crystallised sulphate of cinchonidine | 2.84 | 2.26 | 2.46 | 3.33 |
| Crystallised sulphate of quindine | traces. | traces. | traces. | traces. |
| Cinchonine (alkaloid) | 0.33 | 0.68 | 0.55 | 0.57 |

Dr. King points out that hybrid No. 4 is very poor in quinine, and it was the trees of this sort that were uprooted during the year. No. 7 appears to be exceptionally rich in quinine, and the plantations of this variety might with advantage be extended.

The total number of cinchona trees of all sorts at the close of the year was 4,711,178, namely red (*Cinchona Succirubra*) 3,713,200, yellow (*Calisaya Ledgeriana*) 662,998, hybrid unnamed variety 304,378, and other kinds 30,592.

3. It is satisfactory to observe that the crop of the year is the largest that has yet been harvested on the plantations. It amounted to 398,980 pounds of dry bark, of which 372,610 pounds were of *Succirubra*, 22,120 pounds of *Calisaya* and *Ledgeriana*, and 2,250 pounds of hybrid bark. By far the largest portion of the produce was made over to the factory for conversion into cinchona febrifuge, while about 41,800 pounds of yellow and red barks were sent at the request of the Secretary of State to London to be there converted into various forms of febrifuge, and returned to this country for trial by the Medical Department.

4. The expenditure on the plantations amounted to Rs. 80,739-6-2 against the budget allotment of Rs. 82,225. Of this expenditure Rs. 17,548-3-2 was incurred on the newly opened trans-Teesta plantation, and on the young plantation at Sittong. This sum is chargeable to capital account. The balance, amounting to Rs. 63,191-2-5, which was spent on the old plantation, and includes charges on account of packing and carriage of bark sent to England, is chargeable as working expenses.

5. It is disappointing to notice the continued failure of *Curatagina* bark, notwithstanding that the utmost care has been taken of the plants and every endeavour made to grow them at various elevations and with various exposures. Only three plants were alive at the close of the year. An attempt has been made by the Superintendent to introduce the *Remyia* plant, which is a genus botanically allied to cinchona. It is said to be less particular than cinchona as to soil and climate, and produces a quinine-yielding bark under the name of *Cuprea*. This bark forms a very large proportion of the quantity of quinine bark imported into Europe. Although the first attempt to grow the plant in the Mungpoo plantations has not been quite successful, Dr. King entertains hopes of successfully acclimatizing it, when he is able to procure a more adequate supply of seed. The Lieutenant-Governor will await the result of the experiment with much interest. The surplus seed of the *Calisaya Ledgeriana* was as usual distributed during the year gratuitously amongst applicants.

6. Dr. King has eventually succeeded in obtaining an analysis of the bark renewed on *Succirubra* trees that had their original bark removed by the shaving process introduced by Mr. Moens, the distinguished Director of Cinchona Cultivation to the Dutch Government. It appears that this process consists in shaving off the greater part of the bark of a living tree to the height of from eight to ten feet from the ground, care being taken to leave everywhere a sufficiently thick layer of bark to cover the wood. This method has had a fair trial on the Sikkim plantations, and the result has, beyond doubt, been favourable, as the bark renews perfectly. What, however, remained to be seen was whether the renewed bark was as rich in medicinal alkaloids as the original. It was with the object of determining this question that the analysis above referred to was undertaken during the year. The results are thus described by Dr. King: "The bark renewed rather slowly, but the analysis shows that it is very rich both in quinine and cinchonidine; and there can be no doubt that in countries where red bark trees are perfectly at home, and where their continuance in good health and vigour for a long series of years can be absolutely counted on, this shaving process must be a very excellent one."

7. An interesting feature in the operations of the year is the low cost at which the febrifuge was turned out. The price of the febrifuge necessarily fluctuates from year to year, but in no former year has it been so low as Rs. 8-8 a pound. This satisfactory result is attributed chiefly to the larger percentage of the alkaloids (2.73) extracted from the bark used in manufacture. The issues, however, fell below those of 1881-2, though they were a

little in advance of those for 1880-81. The following table compares the distribution in the past three years:—

| | 1880-81. | 1881-82. | 1882-83. |
|--|----------|----------|----------|
| | Rs. oz. | Rs. oz. | Rs. oz. |
| To Medical Depot, Calcutta ... | 3,000 0 | 3,388 0 | 2,000 0 |
| Ditto, Bombay ... | 2,000 0 | 1,000 0 | 1,000 0 |
| Ditto, Madras ... | 500 0 | 800 0 | 950 0 |
| To Colonial Government, Mauritius ... | | | 150 0 |
| To Surgeon-General for District Medical Officers of Bengal ... | | 995 4 | 908 12 |
| To Inspector-General of Jails for Jails and lock-ups, Bengal ... | | 14 12 | 26 12 |
| Sold to the public ... | 3,150 11 | 4,890 0 | 4,580 12 |
| Given as samples ... | 3 2 | 2 9 | 10 0 |
| Total ... | 8,653 13 | 10,578 9 | 8,901 4 |

The issues to the public were 120 pounds below those of 1881-82, and not in excess of that year as stated in the superintendent's report. The stock of febrifuge in hand, on 31st March 1883 amounted to 2,962½ pounds, which, though greater than that with which the year opened, is by no means too large a reserve to meet emergencies.

The revenue derived from the sale of the febrifuge, seed, plants, and bark amounted to Rs. 1,52,807-1-0—

| | Rs. A. P. |
|--|--------------|
| By sale of febrifuge, seed, plants, and bark to the public ... | 80,577 9 0 |
| By credits from the Medical Depot of Calcutta ... | 33,768 0 0 |
| Ditto ditto ditto of Bombay ... | 16,500 0 0 |
| Ditto ditto ditto of Madras ... | 5,775 0 0 |
| Ditto from Colonial Government of Mauritius ... | 2,475 0 0 |
| Ditto from the Surgeon-General, Bengal ... | 13,271 8 0 |
| Ditto from the Inspector-General, Jails ... | 442 0 0 |
| Total ... | 1,52,807 1 0 |

The operations of the year resulted in a profit of Rs. 66,234-9-5, which is equal to a dividend of 6½ per cent on the capital outlay. This is exclusive of the cost of a considerable quantity of the bark sent to the Secretary of State which has not been taken into account. It must, moreover, be borne in mind that these profits do not represent the whole of the gain of the year. The cost of an equal quantity of quinine at Rs. 96 per pound would have been Rs. 4,01,328. The cost of the febrifuge used was Rs. 68,088-8. There was thus a saving of Rs. 3,32,340. The total saving effected since the opening of the factory by the substitution of the febrifuge for sulphate of quinine amounts to Rs. 23½ lakhs, which is more than twice the amount of the cost of the plantations.

9. Considerable attention was given during the year to the improvement of the process of manufacture. The present system is admittedly wasteful, in that it fails to convert into febrifuge the whole of the alkaloids which the bark contains, while there is no doubt that, by the adoption of a different and more costly process of manufacture, a still larger percentage of the medicinal alkaloids could be extracted. It is not, however, equally certain whether the febrifuge so obtained could be turned out at a less cost per pound. The whole subject of the course to be adopted in the disposal of the raw produce of the plantations is still under the consideration of Government.

10. The thanks of the Lieutenant-Governor are again due to Dr. King, whose management of his department leaves nothing to be desired. Dr. King has reported very favourably of the services of Mr. Gamble, and the Lieutenant-Governor entirely concurs in the praises accorded to him. The other assistants of the department are also well spoken of.

MR. MOENS'S WORK ON CINCHONA.

IN the *Indische Mercur* for 21st June is a review, by Mr. K. W. Van Gorkom, former Director of the cinchona culture in Java, of *De Kincultuur in Azië, 1854 tot en met 1883*, by J. C. B. Moens, Director of the Government cinchona enterprise in Java. We translate the notice as follows:—"With this work, the fruit of years of long study, experiment and observations, the writer has crowned his lengthy rule of the Government cinchona culture in Java. The book, a quarto, printed, with wide margins on thick paper, with full list of contents and alphabetical index, occupying not less than 203 pages, comprises a careful description of the history, culture, harvesting, and botanical as well as chemical peculiarities. The magnificently executed phototypes, taken from nature by Mr. C. Lang, give, by their clear and accurate representations, a still higher value to the entire work. This work, as a whole, both in its contents and in its costly execution, is above our most unqualified praise, and we do not hesitate to recommend it as an excellent standard work, which, in the field of quinquology, surpasses all works which have hitherto appeared, both in fullness and accuracy. And no one was better in a position to furnish us with such a ripe fruit. Engaged since 1872 as chemist to the cinchona culture in Java, and from April 1875 to April 1883 superintending it in its entirety, Mr. Moens had the most favorable opportunity to study both the historical and the practical scientific problems in all their bearings and to place them in a clearer light. A month's visit to the cinchona plantations in British India, extensive and intimate relations with the best quinquologists in Europe, would preserve from prejudice, and the remarkable book, a interesting and indispensable in the highest degree to the planter and the merchant as well as to the merely scientific student, bears on every page the evident traces of wide and at the same time profound views. Science owes special

thanks to the Medical Union of Batavia, who undertook the publication of such a costly work. No library of importance should be without the book. May it be the privilege of the honored and respected writer to continue to utilize his extensive quinquological knowledge still in his native country for the highest interests of culture and of commerce!"

FORESTRY.

TAPPING *PINUS LONGIFOLIA* FOR RESIN.

AS there is some likelihood of a considerable demand arising almost immediately for *Pinus longifolia* resin, the subject of tapping that tree ought to possess no slight interest for the Himalayan forester.

The extensive forests of this pine which stretch along the lower slopes of the outer North-West and Punjab Himalayas have hitherto remained valueless except at a few points, such as Naini Tal, Ranikhet, &c., where the wants of a large local population and the absence or insufficiency of other woods have raised this pine to the position of the chief or sole timber and fuel tree. Not that there is no market for its timber in the numerous wealthy towns situated within a hundred miles of the hills, but present prices are as yet too low, and transport too difficult and costly to make export from these hills pay. Hence every circumstance likely to increase the value of the pine ought to be very welcome. Should the tapping of the tree for resin prove remunerative, the result may be that we shall be able to work several hundred square miles of well-stocked, hitherto unproductive forests, for the conservation of which other forests have at present to pay, and which hence make our financial position appear year after year much worse than it really is, and act as a drag on the progress of the Department.

There is on the surface no reason why the *Pinus longifolia* should not be as important a source of wealth to Northern India as the cluster pine is already to the West of France, even with its present very imperfect means of communication. As in both trees the largest quantity of resin is contained in the sapwood, it is probable that the method employed in tapping the one will suit with little or no modification the other. Readers of the *Indian Forester* will hence perhaps find the following extract from the translation of Bagueris' *Elements of Sylviculture* interesting. It describes the method employed in tapping the cluster pine, and gives some information regarding the amount of yield and price of the resin and its manufacture into the various products used in the arts. The excellent illustrations which accompany are from the pen of Mr. A. F. Brown, who has kindly drawn them at my request for the *Indian Forester* :—

There are two methods of resin-tapping, which in French are termed respectively *gemmage à mort* and *gemmage à vie*. The first exhausts and kills the tree (whence the name), and is adopted only when the tree is to be felled soon after; the second, as may be guessed, has for its object to obtain the resin without causing the death of the tree. In either case, the first thing to be done is to take off gradually a rootangular strip of bark, beginning at the foot of the tree and going up about 4 inches; a little wood must also be removed with the bark. The wound thus made is technically called a *quarre* or blaze. The instrument used is a light axe with a curved head and a handle bent at an angle in the direction of the concave face of the head. Once or twice a week the wound is re-opened, and it is at the same time lengthened by taking off a fresh strip of bark and wood above it about two-fifths of an inch long. In this manner the wound attains a certain length, which in the forests under the control of the Forest Department ought never to exceed 11 feet. Moreover, in the printed stipulations which contractors bind themselves to observe when they purchase the right of resin-tapping, there is a clause which fixed a maximum of 5 inches for the breadth of the *quarre*, and a maximum of two-fifths of an inch for its depth.

"Only one *quarre* at a time ought to be worked in those trees which are not to be felled in the next thinning operations. To prolong their existence, it would even be desirable to make the *quarre* only 3 inches wide. The same *quarre* is worked for 5 years by the process explained above of freshening and lengthening the wound. During the first year it is lengthened by 22 inches; during each of the three succeeding years by 26 inches; and during the fifth year by 28 inches. At the end of this term a new *quarre* is opened which is worked in the same manner. This process is repeated until within a few years of the felling of the trees so tapped, when the process called *gemmage à mort* is employed.

"No tree is tapped in the manner we have just described before it has attained a circumference of 3 feet. M. Lamarque is of opinion that it would be better at the beginning to work a *quarre* for only four years, and then give the tree rest for one year. The *quarres*, when left alone, soon heal up by the formation of new rings of wood and bark, and some time after a new *quarre* may be opened in the swelling formed by the bark immediately over the old *quarre*.

"The swelling is a sure indication of the existence of an old *quarre* beneath, and some old trees may be seen here and there bearing traces of several of them. It frequently happens that from want of sufficient adhesion, the bark separates on each side of the old wounds, the separation being wider at the middle, where also the consequent swelling out of the bark is naturally greater. This phenomenon gives the lower part of the stem the shape of a spindle, and the trunk looks as if it was being crushed under the weight of the portion of the tree above.

"In private forests the *quarres* are often allowed to reach a height of 13 to 16 feet, and two or three are worked at a time on thick trees. This is a bad practice. If for the time being a tree

is made to yield a large quantity of resin, its longevity is materially shortened.

"As we have already indicated, *gemmage à mort* is practised only in the case of trees near their maturity, or of those which are to be felled in the very next thinning operations. It is begun as soon as the trees are big enough to contain a *quarre*, in other words, as soon as they have attained a girth of 20 to 24 inches. This generally happens at the age of 20 years. The *quarres* are opened in precisely the same manner as in the first process, only they are worked up faster, and several at a time are opened in each tree. Usually a tree treated thus dies in three or four years.

"When a new *quarre* is out or an old one re-opened, the resin oozes out in bead-like drops. A portion of it flows down the wound: the rest, owing to volatilisation, solidifies and forms a crust over the exposed wood. This solid substance is known under the name of galipot. Formerly the resin was allowed to run down to the foot of the trees, where it was received in a little trough hollowed out in one of the roots or in the sand. Much of the resin was thus lost by absorption in the sand, especially in the first year. Little earthenware pots are now used, which are hung along the stem of the trees and are raised as the *quarre* is worked up higher. To get the resin to flow into the pots, a small curved plate of zinc is lightly driven in an oblique direction into the wood immediately over each pot. The pot is kept in its place by means of a nail fixed under, and on which it rests lightly. To render the waste still smaller, the pot is covered with a thin board, which prevents the loss of the volatile portion of the resin. The resin-tapper examines the pots when he goes round to re-open the wounds, and empties any he finds full. The galipot is scraped off once or twice a year.

"The use of these pots and plates of zinc constitutes the method of Mr. Hughes. It requires a heavy outlay at first, but it possesses the advantage of yielding a larger quantity of resin, and that in a purer state. According to Mr. Samanos the results of this method, as compared with former results, are as four to three. It is much employed in the Dunes at Cape Breton, Mimizan, Biscarosse, and la Teste. But in the district round Dax its use is not so general, while at Mont de Marsan it is still rare. This is a source of much loss. To diminish the waste of resin by absorption in the soil, the tapper makes the same trough serve for several successive *quarres*. They are consequently obliged to cut little canals all round the foot of the tree leading one and all into the same trough. These canals are necessarily cut right into the wood, and thus soon kill the tree.

"Resin-tapping is carried on only in the interval between the 1st March and the 15th October: but the gradual thinning off of the bark is begun as early as the 10th February.

"Resin is most abundant in trees which measure at least 16 inches in diameter. A pine of this size yields annually three litres by the process of *gemmage à vie*. Taking into consideration the continual diminution in number of the trees, we may reckon that an acre yields annually about 30 gallons, whatever be the age of the forest. It is not so easy to calculate the yield by the process of *gemmage à mort*. Still it is generally admitted that from 80 to 100 pines, 8 inches in diameter, will also yield annually the same quantity, and that for three years. On the estate of M. Marcellus, near Biscarosse, I saw a pine 13 feet in girth and 36 feet high up to the first branch, which had ten *quarres* worked on it simultaneously, and which still yields seven or eight litres of resin annually.

"The price of the raw resin is necessarily very variable. Sometimes it is as low as 40 francs a *barrique* (340 litres). During the American War, it rose to 290 francs. At Mont de Marsan where it is converted into the different manufactured resin products of commerce, the actual price of a *barrique* is 120 francs.

"The resin-tapper is paid so much per *barrique*, usually from 30 to 45 francs; which gives an average of four or five francs a day.

"I visited at Mont de Marsan several distilleries. In one of them they distil the resin for spirits of turpentine. The raw resin always contains, according to the care with which it has been collected, a greater or less quantity of impurities, such as lumps of earth, chips of wood and bark, leaves, &c. To remove these the resin is put into boilers in which it is subjected to a temperature just high enough to liquefy it without causing it to volatilise. In this liquid state it is passed through sieves of rye-straw into troughs. The clear liquid is known under the name of *terebenthine*.

"From the troughs the *terebenthine* is conducted through a pipe supplied with a stopcock into a still. During the distillation, a thin continuous stream of water is introduced into the retort by means of a funnel. The water, in the state of steam, carries over with it the spirits of turpentine, and after condensation in the worm they are both received into a vat.

"They are then separated by the process of decantation. Colophony and black and white resin are made from what remains in the retort. A conduit-pipe leads this residue into a trough, whence it is passed through a very fine brass sieve into a wooden chest; what is collected in the chest is colophony: what is left behind in the sieve is black resin. It is made into cakes of from 100 to 200 lbs., by pouring it while liquid into troughs hollowed out in fine sand. White resin is prepared in the same way, except that the hot residue in the sieve is agitated briskly in one-tenth its volume of water before it is poured out into the sand moulds.

"All these products have their special industrial uses. Spirits of turpentine are employed in medicine, in the preparation of varnishes and paints, for lighting, for cleaning furniture, &c. The solid products enter into the manufacture of paper, soap, stearine candles, torches, sealing-wax, &c., and are also used for the caulking of vessels.

"The residue from the first filtration of the crude resin is burnt in special stoves, and yields tar and pitch.

"One *barrique* of crude resin gives 100 kilos of spirits of turpentine, which, taking actual prices, would be worth about 125 francs; the other products cover all expenses and yield besides a trifling profit. Black resin sells at the rate of 18 francs per hundred kilogrammes; the price of the same weight of white resin is 20 francs.

"In another establishment in the same town, the black resin is heated to a high temperature, by which a double decomposition takes place. The result is, according to the manipulation employed, the separation of certain volatile oils used in varnishes, or of certain fixed oils which are used for lighting, for impregnating wood, in making wheel-grease, in the manufacture of printing-ink, &c."

In the Himalayas the *Pinus longifolia* is already tapped on a small scale, the crude resin being sold in the bazars under the name of *birza*, *ganda phiroza*, *dhup*, *berja*, *lisa*, *khajja*, &c. A small quantity of turpentine is also distilled therefrom for sale in the neighbouring towns. This industry was carried on more extensively before the conservation of the Government forests, since which time the tapping of the pine therein has been strictly forbidden. This is a measure much to be regretted. No doubt the extremely primitive and fatal method of tapping is responsible for the crippling of that very useful industry, but nothing was easier than for the forest officers to teach the hill-men improved methods.

The present system employed in the hills of Kumaun and Garhwal is to cut a sort of niche in the stems of the trees from 3 to 4 feet from the ground. The bottom of the niche is hollowed out into a shallow trough to receive the resin as it oozes out. The trough is cleared out as often as it fills, sometimes as soon as the second or third day, but usually between the fourth and tenth day, when the niche is first made, and at longer intervals afterwards. Generally the resin-tapper does nothing more to the niche once it is made, but as the resin volatilises and hardens over the wound into a crust which impedes the flow of fresh resin, he sometimes chips off the wood on the sides so as to get rid of this crust. The same niche is used for two and even three consecutive years when no forest fire occurs, which either burns down the tree or chars the resin-encrusted wood of the niche to a depth of an inch or more.

Tapping begins in February and ends in May or June, i.e., during the period of comparative vegetative repose. As soon as the buds expand and the tufts of new leaves are developed, the outflow of resin either ceases or becomes too insignificant to be collected. The higher the temperature and drier the weather is, the more copious is the exudation of resin.

As regards the yield per tree, the quantity is very variable according to the size and vigour of the tree, the state of the season, the nature and condition of the soil, and the number of niches cut. As the hill-men never concern themselves about the life of the trees they tap, they work several niches simultaneously, the result being either death by exhaustion or the breaking of the tree by the wind helped by forest fires—a veritable *gemmage à mort*. Mr. Richard Thompson (Brandie's "Forest Flora," page 307) says that "the yield of an ordinary sized tree is 10 to 20 lbs. of *berja* for the first, and about a third of the quantity the second year," in other words, from 13 to 27 lbs. My own information collected in Garhwal and Kumaun gives the yield of a single niche—4 to 6 lbs. the first year, and rather less than a half of that the second year, or from about 6 to 8½ lbs. in all. As a small tree would contain two and a large one three niches, these figures agree pretty nearly with Mr. Thompson's. The largest outflow takes place when the niches are just cut, as much as 1 lb. being sometimes obtained from a single niche from an average sized tree.

If we adopt the system of the French Landes, with the slight modifications, if any, it will require, we shall probably obtain by the method of *gemmage à vie* about the same quantity annually that is now taken out of a single niche during the first year. In other words, there is every reason to expect that the yield per tree in our *Pinus longifolia* forests will be little, if at all, inferior to the yield per tree in the cluster pine forests of the Landes. And we have in our favour cheap labour: the Landes resin-tapper earns from Rs. 1-14 to Rs. 2-6 per day; his Indian *pahari* brother will think himself lucky if he is paid 8 annas a day.

Last year at Naini Tal Mr. Braidwood very kindly supplied me with some crude *Pinus longifolia* resin, from which I distilled essential oil of turpentine, the residue being a pale straw-coloured colophony. The resin was full of impurities (about 5 per cent.) From 3½ gallons I obtained 3 quarts of oil, and about 20 lbs. of colophony. I lost a good deal of the resin in clearing it through a sieve, and the worm of my still leaked very considerably. We shall probably not be far wrong if we assume that the yield of oil under favorable circumstances would be about 30 per cent of the crude resin, or about the same as in the case of the cluster pine.

Some of the essential oil I distilled was submitted by Mr. Greig, the Conservator, to Mr. Morrison, Pharmaceutical Chemist at Naini Tal, for professional opinion. I have not seen Mr. Morrison's written report, but he told me in conversation that he had subjected the oil to the proscribed tests, and had found it, as regards medicinal purposes, equal to the best imported oil, except that its odour was much less pungent. For industrial purposes it will probably be found to be quite as good.

* A much simpler and more effective plan is now followed. A flat plate of zinc with one corner slightly curved upwards, is driven obliquely across the *quarre*, the curved corner being immediately over the pot which is hung on one side of the *quarre*.

* The vitality of *pinus longifolia* is, however, so extraordinary, that in forests from which the resin-tapper has now been excluded during the last 10 years and more, thousands of trees may be seen containing old charred niches. The bark may be stripped off over a breadth of 4 or 5 feet all round the trunk, without necessarily killing the tree.

A proposal has recently been made to use the crude resin for the manufacture of lighting gas, and if the necessary quantity is forthcoming, a trial is to be at once made. Whatever this idea may ultimately come to, some experiments ought certainly to be undertaken in tapping the pine, and manufacturing from the crude resin the various commercial products it can yield. What locality could be more favorable for the purpose than the hill-forests of the School Circle of the N.-W. Provinces? Success, which is assured if the experiments are properly carried out, will result in every *Pinus longifolia* tree, which is now practically valueless, yielding 8 annas yearly, and every moderately well-stocked acre Rs. 15 per annum!

EAST INDIAN FURNITURE WOODS.

TOON WOOD (*Oodrela Toona*) is light, soft, and red, and has no heartwood. It is not eaten by white ants; it is highly valued, and universally used for furniture of all kinds, and is also employed for door panels and carving. From Burmah it is exported under the name of "Moulmein Cedar," and as such is known in the English market. It there fetches about Rs. 65 per ton, the cost of cutting and delivery being Rs. 44, according to Major Seaton. In North-West India, it is used for furniture, carvings, and other purposes. In Bengal and Assam, it is the chief wood for making tea-boxes, but is getting scarce on account of the heavy demand. The Bhutias use it for shingles and for wood carving; they also hollow it out for rice-pounders. It is, or rather used to be—for very large trees are now rather scarce—hollowed out for dug-out canoes in Bengal and Assam. In Bengal, Assam, and Burmah, it grows to a very large size, trees 20 feet girth, with a height of 80 to 100 feet of clear stem, being not uncommon in forests which have been only little worked, like those in Dumsong and in some parts of the Chittagong Hill Tracts.

Chickeraai or Chikraai Wood (*Chikraasia tabularis*) is a large tree, with bark reddish brown and deeply cracked. The heartwood hard, varying from yellowish brown to reddish brown, with a beautiful satin lustre; seasons and works well, and is used for furniture and carving.

Nagesar Wood (*Mesua ferrea*) has dark red heartwood, extremely hard. It has been found to answer for sleepers equally well with Pynkado, but the cost of cutting the hard wood, its weight, and the freight from the Tenasserim forests to Calcutta prevent its being much used, as the total cost is scarcely covered by the price (Rs. 5) per broad-gauge sleeper. It is used for building, for bridges, gunstock, and tool handles; but its more general use is prevented by its great hardness, weight, and the difficulty of working it.

Pitraj Wood (*Ansoora Rohituka?*) is reddish, hard, close and even-grained, but is little used. In Chittagong, canoes are sometimes made of it.

Kandeb Wood (*Ocophyllum polyanthum*) is light red, shining, cross-grained, and moderately hard. It is used largely in Chittagong for masts, spars and rafters, and sometimes for small boat-building and canoes.—*Gambie's Manual of Indian Timbers*.

Tai Wood (*Dichopsis polyantha*) is red and hard, and is much valued in Cachar and Chittagong. Mann says it does not float; but he must refer to green-wood. Major Lewin says it is used in Chittagong for making beds, tools, &c., and is sawn in boards for the Calcutta market.—*Timber Trades Journal*.

There are large tracts of virgin Nagesar forests in the Garo Hills and other parts of Assam, and if the Assam Government would imitate that of the N.-W. Provinces in spending money liberally on roads and timber slides, this large field for enterprise might be opened out. The Meohis are most patient and experienced wood-cutters, and nothing is wanting but proper means of export; and now that the demand for railway sleepers for the projected North-Eastern Frontier Railways is assured, it seems a pity that they should be dependent on Europe for their sleepers, whilst such vast natural resources are close at hand.

Some Toon logs have lately been sent from Dehra Doon to London, to Messrs. Church and Sims, and realised in a sale by public auction 4½d. per superficial foot.

Messrs. Church and Sims report that Toon resembles West India Cedar, but is too hard to be used for the ordinary purposes for which the latter wood is imported, namely, cigar boxes and cabinet work.

Regarding a previous consignment of Toon, however, the same firm reported that it would prove saleable as a substitute for Mahogany, if sent in well squared (sawn, not sawn) logs, about 15 inches square and 12 feet and upwards in length, and would command 2s. 6d. to 3s. per cubic foot. The price lately obtained, £18 16s. 6d., for 112½ cubic feet, was nearly 3s. 8d. per cubic foot, but this is accounted for by the present scarcity of West India Cedar in the London market.

If Toon wood can be delivered in any large quantity at Chittagong or at any Burmese port, it might be profitable to send some trial shipments to London, though of course export from the forests of Northern India is out of the question, both on account of the scarcity of the timber and local demand for it, and also owing to the prohibitive charges for transport by rail to the seaports.—*Indian Forester*.

THE GARDEN.

THE CULTIVATION OF ORCHIDS.

THE cultivation of this highly interesting and beautiful class of plants is not an easy matter, even although India is the home of a great many of them. The largest class are epiphytes, and are found growing on trees, and sometimes on the face of rocks, in the doons and valleys along the base of the Himalayas, and in other hilly parts of the country. The terrestrial species are numerous in the high and more temperate regions, but as there are only one or two species cultivated in gardens on the plains, I do not intend to speak of them at present.

As they are found growing on trees in a natural state, it is also natural to suppose that they will thrive best under cultivation, if nature is imitated as closely as possible. When a garden contains suitable trees, they should always be made use of for orchid culture, but as this is not always the case, artificial methods have to be adopted. When selecting a tree for their culture, seek out one that is full grown; if it is old and beginning to decay, so much the better. Never select a young and vigorous growing tree, as its vigour and growth tends to throw off such encumbrances as orchids. If an orchid is securely tied upon a tree of this class, and regularly watered, it will live for a long time, although it seldom makes enough root growth to cling to it without artificial support. In orchid culture, diminished root growth means scarcity of flowers, therefore we must do all we can to encourage the production of healthy roots. The species of tree to select is also a matter for consideration. The mango is one of the commonest trees in our gardens, and luckily it is one of the best for orchid culture. The jamun, and other rough barked species, are also very good, but I have found that orchids do not establish themselves so quickly upon it, and other species I have tried, as upon the mango. The best season for collecting orchids from the jungle for garden culture is from November to January. They are quite at rest then, and will bear removal without any injury. When you have collected and deposited them safely within your garden, tie them up at once, or plant them in the baskets I have described below. Copper or brass wire is the best tying material, but if not obtainable, strong string may be used. If the roots are slightly covered with moss before running the wire over them, it will be found to be beneficial for retaining moisture, and keeping the wire from cutting them.

Hanging baskets, made from bamboo and blocks of wood, is the two commonest artificial methods of growing them. The first-named I consider to be the better method of the two, and when filled up with nice healthy plants, they always look very ornamental. They are easily made, a common village carpenter will turn out three or four of them in a day. When filling them up, the orchids should be planted in the middle, in a mixture composed of wood chips, pieces of charcoal and moss if obtainable. They thrive best if hung up under the shade of a large tree, but will succeed tolerably well if hung in a verandah. Blocks of wood may be very suitable for damp climates, but in the dry climate of the N.-W. Provinces orchids never look happy upon them. Bamboo baskets should, therefore, be always used in preference. When cultivated in baskets or on blocks of wood, orchids require a greater quantity of water than they ever get in their natural state. When clinging to living trees they probably inhale small quantities of moisture through the bark. The absence of this natural moisture in bamboo baskets, and cut blocks of wood, is probably the cause of a greater quantity of water being required. I may possibly be wrong in my supposition, as a high botanical authority defines the word "epiphyte" as a plant that grows on trees without deriving any nourishment from them. Whether right or wrong, experience proves that water cannot be withheld for months at a stretch under cultivation. Water should, therefore, be given once every day to orchids grown in baskets or on blocks, except during the months of November, December, and January. Three times a week is sufficient during those three months. Those grown on trees should also be watered once a day until they are well established. When they have once taken a firm hold of the tree, they will thrive with less water than required for baskets and blocks.—W. G.—*Indian Forester*.

CULTIVATION OF THE ARTICHOKE.

(Cynara Scolymus L. Compositae DC.)

THIS vegetable is a hardy perennial, a native of Barbary and South of Europe. It appears to have been esteemed as a vegetable from very early times, as Pliny speaks of it as having been cultivated by the Romans. The culinary part is contained in the immature flower heads. The broad fleshy flower receptacle termed the bottom, and the thick base of the horny involucre scales, are the parts eaten. It succeeds with little care and trouble, and is often met with in the gardens of Europeans, but seldom in those of natives.

On the plains the flower heads begin to appear in March, but are most plentiful in April, and continue in season until the middle or end of May. The plants are raised from seed or by suckers. The former should be sown broadcast in beds, from the beginning of August to end of September. The seedlings are very hardy, and seldom suffer from damp; the seeds should, therefore, be sown as soon as an opportunity occurs after the beginning of August. When they have made four or five leaves they are fit for transplanting to where they are intended to be grown. They love a deep and rich soil, and when preparing the ground

for their reception it should be trenched 2 feet deep and liberally manured. When time and labour does not allow of such an effective preparation of the ground, holes 2 feet broad and 2 feet deep should be dug, and the soil thrown back liberally mixed with old manure. The plants should be transplanted at 2½ feet apart, in rows 4 feet asunder. They should be watered regularly, and the soil between the plants occasionally stirred with a fork. When raised by suckers the strongest should be separated from the old plants in September, and at once transplanted at the same distances apart as given for seedlings. They should be annually transplanted in a fresh plot of ground. If this is not done the flower heads decrease in size, and by the third season are all but worthless. It is a good plan to raise one-half of a plot from seeds and the other by suckers. The latter should be annually thrown away after the flower heads are past use, and the former preserved for the production of suckers for the following season. Suckers flower sooner, and the advantage gained is a crop of flower heads a fortnight or three weeks earlier than when seedlings only are used. This vegetable does not degenerate if seed is saved from flowers produced by the leading shoots of the plants raised from seed. A few of the largest flowers should, therefore, be annually reserved for this purpose.

On the hills the plantation need only be renewed every three or four years. When a stock has once been secured from seed, this should be done every third or fourth year by suckers, and the same plan followed as described for the plains. When the plants have to be raised from seeds, these latter should be sown in March or April, and transplanted as soon as they have made four or five leaves. At elevations below 5,000 feet, suckers should be transplanted in September, but above that elevation, and especially if on a northern aspect, it should be done in March or April. At elevations above 6,000 feet, the stools should be protected from frost by a covering of stable litter or half-decayed leaves. In spring, when all danger from frost is past, the covering material should be removed and a quantity of old manure forked in between the plants. During the operation, uncover the stools and remove all the suckers except two or three of the strongest. At lower elevations manuring and removing suckers should be done in autumn; in spring and during their progress, all that requires to be done is weeding and occasional stirring of the soil.

W. G.

—Indian Forester.]

MINERALOGY.

PETROLEUM SUPPLY OF BAKU.—According to a detailed statement on the above subject, lately made before the Berlin Association for commercial progress, by Professor Liebermann, there is at present a remarkable development of activity in the Russian petroleum industry. There are at Baku about 200 small distilling works, and also several large establishments. In the year 1881, there were distilled, at Baku, about 1,400,000 tons of raw naphtha, which yielded about 180,000 tons of illuminating oil.

The most important factory is said to be that of Messrs. Nobel, which has lately extended its operations, and has at the same time increased its capital from £900,000 to £1,500,000. The springs are about eight miles distant from their works, and the transport of naphtha is effected by a five-inch pipe, through which 1,000 tons are daily conveyed to the factory. It is intended to replace this pipe by one six inches in diameter.

The factory produced illuminating oils, in 1880, to the extent of about 22,000 tons; while, in 1891 and 1882, there has been a progressive augmentation to 50,000 tons and 90,000 tons. It is calculated that a further considerable increase of production may be expected during 1883 and 1884.

ASPHALTE DEPOSITS IN MEXICO.

A VARIETY of bituminous substances, from the pure hard asphaltum to the fluid petroleum, are known to exist in immense quantities along the coast of the Gulf of Mexico, chiefly in the States of Tamaulipas, Vera Cruz, and Tabasco, but there appears to have been no organised efforts to utilise the deposits, either for domestic purposes or for commerce. Consul Cassard, of Tampico, says that almost inexhaustible beds of asphaltum exist on both banks of the river Tamacuil, about sixty miles above that port, being found in a comparatively pure state and containing only an insignificant proportion of foreign matter, chiefly vegetable which it gathers while through cozing the sedge borders of the river. The substance may be gathered with little difficulty, but as the locality is only accessible to boats of light draught, the beds are comparatively neglected. Asphaltum, or *chapopote*, as it is called in Mexico, is frequently found floating in masses on the rivers and lagoons, and is cast up on the beach by the waves all along the Gulf Coast, and especially in the vicinity of Taxpan, and on the Grijalva river in Tabasco. These masses, by the local law of flotation, are the property of the finder, and are sold at the rate of from eight to nine shillings the hundred weight. In the state of Vera Cruz asphaltum is found in considerable quantities, the principal deposits being in the canton of Jalacingo, in Minatitlan, in the canton Orizaba, where several deposits of petroleum, asphaltum, and coal are known to exist in a place called El Chapopote, in the municipality of Panuco, in Papantla, in Taxpan, and Temtoyaca. In Vera Cruz, near the village of

Molacuan, a few miles distant from the river of Coahuacillas, there is an immense deposit of asphaltum, which, at some places, is found pure and at others more or less mingled with rock salt and sulphure. According to Dr. Hochler, a German traveller who visited it, the "salt mine," as it is popularly called, is an isolated spur, branching off from the main ridge, or cordillera. This mountain is from 1,000 to 1,200 feet in height, and with a base of from three to four miles in extent, of cone shape and cracked by earthquakes; on its slopes are found a number of pits, some cold and still, others seething and bubbling, and emitting a stifling odour. These pits appear to have cavernous communication with the internal fires of the mountain, which, as indicated by the external heat and frequent subterranean noises, contain vast masses of material in a state of combustion. The whole adjacent surface consists of asphaltum partly solid, and partly liquid, and more or less mixed with rock salt. So extensive are these beds that the supply may be considered inexhaustible. In some places the seething pits eject considerable quantities of asphaltum in a liquid state. Extensive beds are also known to exist in the State of Chiapas, on the upper waters of the Grijalva river, which has its course through the State of Tabasco, and empties into the Mexican Gulf, near Frontera.

TOBACCO.

FRENCH TOBACCO STATISTICS.—The consumption of tobacco in France is rapidly increasing, and last year showed no exception to the rate of progression, the quantity consumed amounting to 941 grammes (about 21 lbs.) per inhabitant, and presenting a value of 9fr. 76c. (7s. 9½d.). In 1881 the quantity consumed was 925 grammes (20½ lbs.) per inhabitant; in 1880, 907 grammes (under 20 lbs.); in 1875, 855 grammes (under 19 lbs.), worth 8fr. 58c. (6s. 10½d.). According to the returns of the indirect taxes direction, the sales in France during 1882 produced the following amount:—Tobacco for smoking, 164,930,180fr. (£8,597,207); of inferior quality, 23,809,577fr. (£928,383); common carotte, 5,765,870fr. (£230,934); cigars, 57,758,948fr. (£2,310,358); for chewing, 8,617,610fr. (£344,704); cigarettes, 16,767,318fr. (£670,692); and snuff, 78,229,507fr. (£3,139,180); making a total of 355,339,019fr. (£14,313,560).

TOBACCO-GROWING.

MR. W. W. SANDERSON, of South Deerfield, Mass., in a letter to the *Tobacco Leaf*, gives some of his experience as a tobacco grower as follows. He says:—

My success in growing this variety is due more to improvement in quality of seed and careful cultivation than all other items. I have grown Havana seven years and in only one instance (and then one-half acre) have I obtained less than one ton to the acre. I take run-out grass land, and plough it soon after haying very shallow, and plough again seven or eight inches deep just before the ground freezes, and then apply two or three bushels of dry slaked lime, and in the spring harrow thoroughly, and in May plough in ten or twelve cords of good barn-yard manure. When the plants are nearly large enough to set out, harrow fine, and furrow out rows three feet apart, and strew about two or three cords of fine manure in the furrow and five to eight hundred pounds of Peruvian guano, and cover this with a ridger that will leave the hills 22 inches apart. The fertilizer must be nearer the plants than for seed land. Keep clean and cultivate often, and have soil loose between the rows.

Sucker clean and top high. A good or perfect crop cannot be secured unless it is suckered clean, as suckers suck the juice absolutely necessary to perfect the leaves.

Let it stand four weeks or more to ripen after topping, and hang with twine or hooks, as Havana is hard to lath, and, besides, cures too quick. The slower and darker it can be cured the better. Do each part carefully and well.

Take down and strip only when in just the right condition and make neat single bundles of ten to twelve pounds each. Tie with two strings if Havana, and three if Seed leaf, keep the butts even and tips straight, and you can always sell at a good price in the bundle.

I always sell in the bundle at from 16 to 20 cents, and others can do as well, if not better.

About ten years ago I believed improvement could be made in tobacco by selecting in some way the best seed, and adopted the following method, which proved my theory with Seed leaf, and for the past seven years with Havana Seed: Select best plants, remove all suckers, and when a few of the earliest seed pods turn brown, remove all the blossoms and seed pods not full ripe, and the strength of the plant is concentrated in making the seed plump and strong, instead of large in quantity. When the seed is ripe, shell it, and then carefully winnow it several times, removing from 1 to 2 of the lightest seed, causing the plant to give you the most perfect seed. By this method you get a better quality and more weight.

I have sold large quantities of seed raised in this way, and it always gave satisfaction. I read a paper this past winter to an audience of Suffield tobacco growers, which I hope will result in helping to regain the reputation of the Connecticut tobacco. At present Seed leaf will not supply the demand for fine wrappers, and Havana Seed will, being far superior in flavor and quality, and nearly equal in wrapping capacity to Sumatra. I have used first, second, third, fourth and tenth year's growth of Havana Seed, but recommend the tenth year's growth.

FIRE BRICKS.

RANEENGUNGE FIRE BRICKS as supplied to Government and the various Railways, Iron Works, Coal, Gas, and Steam Navigation Companies. Price—Rs. 9 per 100.

Extract from Official Report of tests made at H. M's Mint, Calcutta, by THEODORE W. H. HUGHES, Esq., F.C.S., A.R.S.M., Officiating Deputy Superintendent, Geological Survey, India:—

"The Fire Bricks tested by me were furnished by the Firm of Messrs. BURN & Co. * * * The materials from which they are made are very refractory and capable of resisting high temperature without sensibly fusing. * * * That compared with Stourbridge Fire Bricks are somewhat superior."

The specimens were subjected to a temperature of over 3,000 degs. Fahr., the smelting point of Cast-iron being 2,786 degs. Fahr.

Apply for the above, and for Raneengunge Salt-glazed Stoneware and Imperishable Drainage Pipes, to

BURN & CO.,

7, Hastings-street, Calcutta,

or Raneengunge Pottery Works, Raneengunge,

E.I.R., Bengal.

FRANCE.**CONTINENTAL & COLONIAL AGENCY,**
(LICENSED),

14, RUE DE CHABROL, PARIS.

Transacts every description of Commission, Merchant, and General Agency Business.

All Indents executed at Manufacturers' most favourable terms.

Conditions.—Two and a-half per cent Commission when Bankers' Draft on London or Paris accompanies order. Special terms to regular correspondents. All Discounts conceded to purchasers. Original Invoices sent when required.

Produce taken charge of and realised to best advantage. Cash advanced on Consignments.

The Agency Represents, Buys, and Sells for Firms.

Public Securities, Estates and Properties, bought and sold. Loans, Mortgages, Mines, and Industrial Investments, &c., negotiated.

Manufacturers and Producers can have suitable articles introduced to the markets on advantageous conditions.

PRICE LIST—comprehensive and reliable—on application.

BANKERS.—PARIS: George Waters, Esq., 30, Boulevard des Italiens. LONDON: The London and County Bank, 3, Victoria-street, Westminster.

Address: The Manager, Continental and Colonial Agency, 14, Rue de Chabrol, Paris, France. 447

ZULULAND AND CETEWAYO.

"'I know what it is,' he answered; 'this honey is made from euphorbia flowers, which are very poisonous.' This explanation made me feel exceedingly uncomfortable; but I elicited from him that there was not much danger, as the 'maass' taken with it would neutralise the effect of the poison. Directly he mentioned poison I dived into the packs, and pulled out a bottle of ENO'S FRUIT SALT, and emptying a quantity into two pannikins, filled them up with water, and several times repeating the dose, in a few hours we were considerably better."—*"Zululand and Cetewayo," (p. 159), by Captain W. R. Ludlow, 1st Batt. R.V. Royal Warwickshire Regiment.*

"'What on earth shall I take to Zululand?' asked my friend Jim Law one day at Aldershot, when he had just received orders for South Africa, to start at forty-eight hours' notice. I replied, 'If you take my advice—and it's that of an old traveller—you'll not budge without a few bottles of ENO, even if you leave half your kit behind. I never am without these Salts, and, please the pigs, never intend to be.' On his return I inquired, 'Well, how about ENO'S FRUIT SALT?' 'My dear fellow, it was the best advice you ever gave; they saved me many an illness; and when I left Tuegia, I sold the remaining bottles for ten times the original price!'"—*Lieut.-Col.*

JEOPARDY OF LIFE. THE GREAT DANGER OF DELAY.

You can change the trickling stream, but not the raging torrent.

WHAT EVERYBODY SHOULD READ.—How important it is to every individual to have at hand some simple, effective, and palatable remedy, such as ENO'S FRUIT SALT, to check disease at the outset! For this is the time. With very little trouble you can change the course of the trickling mountain stream, but not the rolling river. It will defy all your tiny efforts. I feel I cannot sufficiently impress this important information upon all Householders, or Ship Captains, or Europeans generally, who are visiting or residing in any hot or foreign climate. Whenever a change is contemplated, likely to disturb the condition of health, let ENO'S FRUIT SALT be your companion; for, under any circumstances, its use is beneficial and never can do harm. When you feel out of sorts, yet unable to say why, frequently without any warning you are suddenly seized with lassitude, disinclination for bodily or mental exertion, loss of appetite, sickness, pain in the forehead, dull aching of back and limbs, coldness of the surface, and often shivering, &c., &c.; then your whole body is out of order, the spirit of danger has been kindled, but you do not know where it may end: it is a real necessity to have a simple remedy at hand that will answer the very best end, with a positive assurance of doing good in every case and in no case any harm. The pilot can so steer and direct as to bring the ship into safety, but he cannot quell the raging storm. The common idea when not feeling well is, "I will wait and see, perhaps I shall be better to-morrow;" whereas, had a supply of ENO'S FRUIT SALT been at hand, and use made of it at the onset, all calamitous results might have been avoided. What dashes to the earth so many hopes, breaks so many sweet alliances, blasts so many auspicious enterprises, as untimely death?

ENO'S FRUIT SALT.—"After suffering for nearly two and a half years from severe headache and disordered stomach, and after trying almost everything and spending much money without finding any benefit, I was recommended by a friend to try ENO'S FRUIT SALT, and before I had finished one bottle I found it doing me a great deal of good, and now I am restored to my usual health; and others I know that have tried it have not enjoyed such good health for years.—Yours most truly, ROBT. HUMPHREYS, Post Office, Barrasford."

SUCCESS IN LIFE.—"A new invention is brought before the public, and commands success. A score of abominable imitations are immediately introduced by the unscrupulous who, in copying the original closely enough to deceive the public, and yet not so exactly as to infringe upon legal rights, exercise an ingenuity that, employed in an original channel, could not fail to secure reputation and profit."—*ADAMS.*

CAUTION.—Legal rights are protected in every civilised country. Examine each Bottle, and see the capsule is marked "ENO'S FRUIT SALT." Without it you have been imposed on by worthless imitations. Sold by all Chemists, price 2s. 9d. and 4s. 6d.

THE ART OF CONQUEST IS LOST WITHOUT THE ART OF EATING.—DINNER ENGAGEMENTS.—STIMULANTS.—TOO RICH FOOD.—LATE HOURS.—INSUFFICIENT EXERCISE.—EXCITEMENT, &c.—A gentleman writes: "When I feel out of sorts, I take a dose of ENO'S FRUIT SALT one hour before dinner or first thing in the morning. The effect is all I could wish." How to enjoy good food that would otherwise cause biliousness, headache, or disordered stomach—use ENO'S FRUIT SALT.

DIRECTIONS IN SIXTEEN LANGUAGES HOW TO PREVENT DISEASE.

Prepared only at ENO'S FRUIT SALT WORKS, HATCHEM, LONDON, S.E., by J. O. ENO'S Patent.

PHOENIX IRON WORKS, CALCUTTA.

THE OLDEST ENGINEERING ESTABLISHMENT IN INDIA, JESSOP & CO.,

Civil and Mechanical Engineers, Contractors, Brass and Iron Founders,
Metal Merchants, &c.

*Forged and Cast Iron Work, Boilers, Machinery for Jute, Cotton and Rice Mills, Collieries, Indigo Concerns, Tea Gardens, &c.,
Contractors' and Brick-making Plant, and every class of Iron and Brass Work made to order.*

SOLE AGENTS FOR

Robey & Co's celebrated Portable and Fixed Engines and Machinery, Gwynne & Co's "Invincible" Centrifugal Pumps, Gould's Rotary Pumps, and Robinson's Patent Steam Traps.

IMPORTERS AND MANUFACTURERS OF EVERY DESCRIPTION OF STEAM ENGINES AND MACHINERY.

Robey & Co's Portable, Horizontal, Fixed, and Patent "Robey" Semi-fixed Engines, Combined Vertical Engines and Boilers, Land and Marine Boilers, Gould's Rotary Power Pumps, J. & H. Gwynne's "Invincible" Centrifugal Pumps, Hand, Lift and Force Pumps, Tangye's "Special" Steam Pumps, "Vauxhall" Donkey Pumps, Flour Mills, Saw Benches, Spencer's Hand Drilling Machines, Steam Pressure Recorders, Richards' Engine Indicator, Gifford's Injectors, Cooking Stoves, Fire-Proof Safes.

J. & H. Gwynne's "Invincible" Centrifugal Pump.

This Pump being arranged to swivel on the bed-plate may be fixed at any angle required. It does not require a foot-valve, being fitted with small air exhauster and check on discharge, which always keep it charged ready for work.

Robey's Combined Vertical Engine and Boiler.

This class of Engine is nearly twice as large as those of the same nominal horse-power of some makers. The Engine, instead of being fixed to the Boiler as is usual in Engines of the same class, is erected on a massive Cast Iron Standard which makes it quite independent of the Boiler.

Ransome's "Indian" Plough, price—Rs. 15.

These Ploughs have been expressly designed and manufactured for the use of the Ryots of India, whose special needs have been carefully studied in their construction. They embody all the qualifications for which the native-made implements have hitherto been preferred, whilst being incomparably superior in strength, durability, and efficiency.

MORAE'S PATENT SUB-SOIL AND GENERAL PLOUGH

Stirs up the soil to three times the depth of a native plough, and leaves the good mould on the top. Goes through the dirtiest land without getting choked with weeds. Price, Rs. 15.

INDIGO AND TEA PLANTERS' IMPLEMENTS AND STORES.

ENGINEERS' TOOLS AND STORES OF ALL KINDS.

ALWAYS ON HAND A LARGE STOCK OF PLATE, BAR, ANGLE, TEE AND CORRUGATED IRON, STEEL, BRASS, COPPER, PIG IRON, FOUNDRY COKE, SMITHY COAL, FIRE BRICKS, AND FIRE CLAY.

New York, 1880. Berlin, 1879. Melbourne, 1880. 1878. Cincinnati, Ohio, 1880.

OVER 450,000 FEET SOLD DURING 1881.

Including 3,877 feet of main Driving Belts, of widths ranging from 12 in. to 60 in., are working in over 6,000 Mills and Works in Europe and America.

The following Tests (by Kirkbaldy, of London) show the relative strength and value compared with Leather.

| | Breaking Strain per Square Inch of Section. | Price per foot. |
|-----------------------------------|---|-----------------|
| Best Double Leather 6 in. Belting | 3,572 lbs. | 2s. 7d. |
| Gandy's 6 in. x 8-ply Cotton | 6,811 lbs. | 2s. 6d. |

THE GANDY BELT.

Any Length or Width for Main Driving.

It is the best belt ever made for all purposes. Much Cheaper and Stronger than Leather. Thoroughly Waterproof, and not affected by temperature, clings well to the pulleys, runs true, and can be made any length without joints.

This Series of Belting (see engraving) was supplied in One Order to Messrs. John Crossley and Sons, Halifax, May 1, 1880, and continues to give entire satisfaction.

THE "GANDY" BELT.

GANDY'S Patent American Cotton Belting was given a superiority over leather in every particular; its cost is being about half that of leather, while its strength and gripping power is about as high as the best leather, as shown by repeated tests taken by Kirkbaldy, of London. These tests are given above, to which special attention is directed. These "Gandy" belts are made of any width up to 72 inches, and any length up to 840 feet without joint, thus obviating the necessity of having two belts on the same pulley, a system of driving which is never satisfactory, as it is impossible to have belts of exactly the same tension; hence one or the other is always causing a stoppage. These stoppages are avoided by using Gandy's Patent Belts in one width. These Gandy Belts are made of the finest American Cotton Duck, specially prepared in Baltimore for the purpose, and then put together and finished by Gandy's patented special Machinery and process to prevent stretching, and render them impervious to atmospheric influences. A number of advantages such as these, the universal adoption of Gandy's Belts can only be a question of time.

A SUBSTANTIAL GUARANTEE GIVEN WITH EVERY MAIN DRIVING BELT.

U.S.A.

GREAT REMEDY FOR PRICKLY HEAT, INDIGESTION, HEADACHE, BILIOUSNESS, AND FEVERS.

The testimony of medical gentlemen has been unqualified in praise of

LAMPLOUGH'S PYRETIC SALINE,

As possessing elements most essential for the restoration and maintenance of health with perfect vigour of body and mind.

It is Effervescing and Tasteless; forming a most Invigorating, Vitalising, and Refreshing Beverage.

Gives instant relief in HEADACHE, SEA or BILIOUS SICKNESS, CONSTIPATION, INDIGESTION, LASSITUDE, NEURALGIA, and FEVERISH COLIC; prevents and quickly cures the worst forms of TYPHUS, SCARLET, JUNGLE, and other FEVERS, SMALLPOX, MEASLES, and ERUPTIVE or SKIN COMPLAINTS, and various other altered conditions of the blood.

Dr. FROST:—"Unfolding terms of immense benefit to mankind."

Dr. MORGAN:—"It furnishes the blood with its lost saline constituents."

GOVERNMENT OFFICIALS AND PLANTERS caring for the welfare of their employees should note its value as a specific in Fever cases.

Dr. J. W. DOWLING:—"I used it in the treatment of forty-two cases of Yellow Fever, and am happy to state I never lost a single case."

Dr. W. S. BAYLY:—"Since its introduction the Fatal West India Fevers are deprived of their terrors."

HIS MAJESTY'S REPRESENTATIVE the GOVERNOR OF SIERRA LEONE, in a letter of request for an additional supply of the Pyretic Saline, states:—"It is of great value, and I shall rejoice to hear it is in the houses of all Europeans visiting the tropics."

Dr. SPARKS (Government Medical Inspector of Emigrants from the Port of London) writes:—"I have great pleasure in bearing my cordial testimony to its efficacy."

Dr. SPARKS (Government Medical Inspector of Emigrants from the Port of London) writes:—"I have great pleasure in bearing my cordial testimony to its efficacy."

Dr. SPARKS (Government Medical Inspector of Emigrants from the Port of London) writes:—"I have great pleasure in bearing my cordial testimony to its efficacy."

Dr. SPARKS (Government Medical Inspector of Emigrants from the Port of London) writes:—"I have great pleasure in bearing my cordial testimony to its efficacy."

Dr. SPARKS (Government Medical Inspector of Emigrants from the Port of London) writes:—"I have great pleasure in bearing my cordial testimony to its efficacy."

Dr. SPARKS (Government Medical Inspector of Emigrants from the Port of London) writes:—"I have great pleasure in bearing my cordial testimony to its efficacy."

To be obtained of any Chemist or Drug Store, in Patent Glass-stoppered Bottles, 2s. 6d., 4s. 6d., 11s., and 21s. each. Please note in connection with the recently observed effects of the use of Citrate and other preparations of Magnesia that LAMPLOUGH'S PYRETIC SALINE is warranted not to contain any substance which would cause calculous or other earthy deposits.

PHOENIX IRON WORKS,

CALCUTTA.

THE OLDEST ENGINEERING ESTABLISHMENT IN INDIA, JESSOP & CO.,

Civil and Mechanical Engineers, Contractors, Brass and Iron Founders,
Metal Merchants, &c.

*Forged and Cast Iron Work, Boilers, Machinery for Jute, Cotton and Rice Mills, Collieries, Indigo Concerns, Tea Gardens, &c.,
Contractors' and Brick-making Plant, and every class of Iron and Brass Work made to order.*

SOLE AGENTS FOR

Robey & Co's celebrated Portable and Fixed Engines and Machinery, Gwynne & Co's "Invincible" Centrifugal Pumps, Gould's Rotary Pumps, and Robinson's Patent Steam Traps.

IMPORTERS AND MANUFACTURERS OF EVERY DESCRIPTION OF STEAM ENGINES AND MACHINERY.

Robey & Co's Portable, Horizontal, Fixed, and Patent "Robey" Semi-fixed Engines, Combined Vertical Engines and Boilers, Land and Marine Boilers, Gould's Rotary Power Pumps, J. & H. Gwynne's "Invincible" Centrifugal Pumps, Hand, Lift and Force Pumps, Tangye's "Special" Steam Pumps, "Vauxhall" Donkey Pumps, Flour Mills, Saw Benches, Spencer's Hand Drilling Machines, Steam Pressure Recorders, Richards' Engine Indicator, Gifford's Injectors, Cooking Stoves, Fire-Proof Safes.

J. & H. Gwynne's "Invincible" Centrifugal Pump.
This Pump being arranged to swivel on the bed-plate may be fixed at any angle required. It does not require a foot-valve, being fitted with small air exhauster and clack on discharge, which always keep it charged ready for work.

Robey's Combined Vertical Engine and Boiler.
This class of Engine is nearly twice as large as those of the same nominal horse-power of some makers. The Engine, instead of being fixed to the Boiler as is usual in Engines of the same class, is erected on a massive Cast Iron Standard which makes it quite independent of the Boiler.

Ransome's "Indian" Plough, price—Rs. 15.

These Ploughs have been expressly designed and manufactured for the use of the Ryots of India, whose special needs have been carefully studied in their construction. They embody all the qualifications for which the native-made implements have hitherto been preferred, whilst being incomparably superior in strength, durability, and efficiency.

MORAE'S PATENT SUB-SOIL AND GENERAL PLOUGH

Stirs up the soil to three times the depth of a native plough, and leaves the good mould on the top. Goes through the dirtiest without getting choked with weeds. Price, Rs. 15.

INDIGO AND TEA PLANTERS' IMPLEMENTS AND STORES.

ENGINEERS' TOOLS AND STORES OF ALL KINDS.

ALWAYS ON HAND A LARGE STOCK OF PLATE, BAR, ANGLE, TEE AND CORRUGATED IRON, STEEL, BRASS, COPPER, PIG IRON, FOUNDRY COKE, SMITHY COAL, FIRE BRICKS, AND FIRE CLAY.

Catalogues on Application.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah in particular varies so much in the different provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

All correspondence must bear the full name and address of the writer, not necessarily for publication, but as a guarantee of good faith. We shall take no notice of anonymous letters.

CORRESPONDENCE.

INDIAN SUGARCANES.

TO THE EDITOR.

SIR,—Could you or any of your correspondents inform me if there is any standard work, or scientific authority which would enable me to obtain a correct identification and the technical nomenclature of the different kinds of sugarcane grown in India? The author of *Tropical Agriculture* enumerates more than thirty different kinds grown in India, China, Mauritius, Bourbon, Africa, Australia, Egypt, West Indies, North and South America. Herr Schrotsky in his work mentions two or three distinct species, but it does not appear whether they are identical with any grown in Northern India.

In this, the (Jullundhur) Doab, there are I know six distinct kinds met with, viz., *Chann*, *Kanara*, *Ekar*, *Dhau*, *Kahu*, and *Panna*.

(1.) The *Chann* is a thin slender cane with a pale brown color streaked with purple, rich in juice, and saccharine matter, the juice, having in well cultivated lands, an average density of 10.5° Beaumé.

(2.) The *Kanara* in native estimation ranks next to the *chann*, but is cultivated chiefly in the submontane tracts, the Siwaliks, and lower valleys of the Kangra districts. It is softer to crush, is rich in juice and saccharine matter, and has a pale, greenish color, and gives a very fair sugar.

(3.) The *Ekar* is a very inferior description of cane, hard to crush, and its cultivation is being generally discontinued throughout the Doab.

(4.) The *Dhau* ranks next to the *kanara*; it attains a much larger size than the three preceding varieties, it has a pale green color, hard to crush, rich in juice, but deficient in saccharine matter, juice rarely if ever exhibiting a greater density than 7.5° Beaumé. The *dhau* is, as far as I was able to ascertain from comparison with some specimens of cane specially procured from the Aligarh District, identical with a kind known down-country as *Saharanpuri*.

(5.) The *Kahu* is grown extensively in the Bari Doab, more especially in the Goordaspore district, it has been introduced into the Dosuryah tahsil (Hoshiarpore district) and was tried for the first time in the experimental farm at Hoshiarpore at the instance of Mr. Coldstream, the then Deputy Commissioner. It attains a large size, about three inches in circumference, with a height varying from eight to nine feet; the color is a pale green, streaked with violet or purple. The yield in juice is good, and the juice has an average density of 10.5° Beaumé. I may add that the experiment of last year was conducted on a small area, not more than 0.17 of an acre, and the results which were good should on that account be received with caution: this year's crop will enable us to see whether the heavy outturn of last season, 57 maunds or 5,360 lbs. of goor to the acre, was merely an accident, due to the unsafe practice of calculating produce off small areas, and accepting the results as reliable factors for general application.

(6.) The *Panna* is grown all over the Punjab but seldom for conversion into sugar, generally being reserved for use as a sweetmeat to be eaten raw. It is too well known to need description here, but the question has often suggested itself—Why do not the natives crush it for sugar? It attains a large size, very juicy and sweet. It is a very expensive crop to cultivate, inasmuch as it requires an enormous amount of water to bring it to maturity.

The *chann*, *kanara*, *dhaul*, and *ekar* can all be grown on good land without much irrigation, the ordinary rainfall being generally sufficient to develop the crop; whereas *kahu* requires watering at least once every ten days during May and June until the rains set in, and should get at least two waterings between October and the end of December in order to preserve it from frost.

The cultivation and preparation of the land is the same for each kind, but I found that whereas an acre of *chann* can be sown with 20 it takes 40 maunds of seed to sow an equal area with *kahu*.

In converting the *kahu* into *goor*, a *Mylne and Thomson's* mill was used, evaporation and concentration, if such it can be termed, being effected in a *karaha* or open pan.

It was found that the ratio of juice to cane was on average 72.75 per cent, which was of course very good.

The juice was strained through thick cloth at first, but latterly through *flannel*: it was then emptied into a space *karaha*, treated with one ounce of slaked and screened lime, well pulverized, made into a cream with water; a *slow* fire maintained until the *rum* and all mechanical impurities present had risen to the surface: the juice was then emptied into another pan and a steady fire of *margam* and cotton stalks maintained, until the proper degree of concentration, about 25 Beaumé was arrived at; it was then run off into a cooler and allowed to attain the crystallized mass and formation known as *goor*. It had a bright *golden* colour, presenting a marked difference to the *goor*, clarified with *siklani*.

Siklani is the bark of the *acacia arabica*, "*babul*," pounded up and made into a paste with water.

A considerable amount of chemical impurities must remain in all juice so nicely clarified, animal charcoal on defecation by *sulphurous acid gas* being the most efficient means hitherto used to remove the fecula, wax, and to neutralize completely the salts of potash, soda, and magnesia existing in cane juice.

Another great defect in the native method of *open pan* evaporation, is the waste of fuel and the great heat applied to the juice during concentration: in a *vacuum pan* the temperature rarely exceeds 150° Fahr. (65.5 Cent), hence the superiority of the sugar, the large volume and well defined form of the crystals.

The results obtained during the experiments on the *kahu* have impressed the natives with the idea that it is a staple worthy of more general and extended cultivation. And there are grounds for assuming that in course of time this variety will to a great extent supersede the *chann* which is now most generally cultivated.

If there is one industry more than another which should attract English capital into India it is sugar, labor and fuel being cheap, and practically no competition, there being only two *usines* in the whole of Northern India—Shahjehanpore, and Sujampur on the Barce Doab Canal.

A small *usine* capable of turning out 5 tons of sugar per diem, on the produce of about 3 acres, equal to say 150 tons of sugar per mensem, would, if properly managed, yield a very fair profit: considering that French *usines* in *Martinique*, and English factories in *Jamaica* and *British Guiana* have, where fuel and labor are dearer than in India, been known to yield as much as 25-30 per cent on *paid-up* capital, there is no reason to assume that an equal measure of success should not be attainable in Upper India.

A properly conducted *usine* should be able to supply good sugar to the people at large and turn out a fair drinkable liquor. If the Aryan brother is to get drunk, it is far better that he should get drunk on good sound *cane-rum*, than on the adulterated abominations sold in the *bazaars*.

That the establishment of a sugar factory in the heart of a sugar-producing district would be an unequalled blessing to the cultivators, is a question not admitting of a single doubt.

A native *belua* will work off an acre of sugar-cane, or say 40,000 lbs. of cane in about 45 days, the boiling, cooling and other processes taking an interminable time, the refined sugar not coming into the market till about the following May.

A native *belua* has not a higher extractive power than 53.80 percent, so that assuming an acre of sugarcane to weigh 40,000 lbs., we should get 24,000 lbs. of juice, and allowing 8 per cent of this to be dry sugar we get 1,920 lbs. as the gross outturn, and $1,920 \div 24 = 80$ maunds sugar, selling, say at 16 per maund, total value—Rs. 354.

An English machine turned out by any good maker, such as M. M. Walker Henderson and Co., Glasgow, Buchanan & Co. London, or other large firms too numerous to mention, will give an

extractive power, or rather and more correctly speaking, give an extractive power nearly 80.85 per cent, so that for our 40,000 lbs. of cane we should get 32 per cent of juice, or 32,000 lbs. and what is more of a higher density than from the native *belua*, so that we might calculate on something like 2,500—2,750 lbs of dry sugar, which would be (at the same rate as before) worth Rs. 500.

Hence, irrespective of the very important consideration of cheapness of manufacture, the *usine* can get more out of an acre of cane than the zemindar or village *shah*, consequently the *usine* can afford to pay more for the cane than the native manufacturer.

But the advantage to the zemindar does not cease here. It takes him nearly six weeks to work off his acre of cane, whereas a *usine* such as I have described would run this cane off in *half as many hours* with the greatest ease—in fact, faster than the cultivator could supply it even with 20 carts working. The aquatic weeds alluded to by your correspondent in your last issue, when discussing the sugar-producing capabilities of the Doab, are *Vallisneria spiralis* and *Potamogeton crispus*.

Let us hope, now that our Aryan brother is about to be politically educated by means of *Local-Self-Government* and *Native Jurisdiction Bill*, his intellectual and social education may be taken in hand as well, and that he will be able to dispossess his mind of many prejudices which preclude his availing himself of the advantages modern science places at his disposal, he may then ascertain for himself the important truth that there are easier means of winning purgatory and courting social ostracism than by eating sugar, refined by animal charcoal.

C. S. F.

EXTRAORDINARY CASE OF A BUFFALO-COW SWALLOWING A STEEL SPINDLE.

TO THE EDITOR.

SIR,—The following particulars of this unusual case may interest veterinary readers:—

On the 11th of July last, a buffalo-cow in very prime condition and about seven months gone in calf, the property of a cultivator in the Agra district, N.-W. Provinces, finding herself near a spinning wheel, and prompted no doubt by her evil genius drew out the steel spindle by the roll of newly prepared thread that was on it, with the intention of eating the thread only we presume, but in swallowing this she took down the spindle with it.

Great was the distress of the owner, for she was of a valuable breed. "Ah! unfortunate," he was heard to say, "I suspected that your vile habit of making a masticatory of every bit of cloth and paper you came across would bring you to grief in some way, but little did I think it would lead you to swallow a sword." All the cow-leeches in the neighbourhood were appealed to, but their pathology contained no rules for the treatment of such a case, and the only consolation he received was, that cattle generally died when they swallowed a needle only two inches or so in length, and that cattle-poisoners found that throwing a needle into the fodder of their intended victims was one of the safest ways of ensuring their demise.

Left to his own resources he ground down some load-stone, and made the cow drink it; not that he thought that it would do much good, but simply because he was hanged if he could think of anything else. He also went to great pains to secure a large horse-shoe magnet, and was found in the act of moving it about her body in a listless manner in the hope forlorn that the spindle would be attracted out.

For the first 8 days she would not eat anything, and for 10 days after was kept alive by hand-feeding with wheat chaff, for she would not touch grain of any sort; after this she commenced eating herself, but only a little green grass and wheat chaff. By the 9th September, 60 days after swallowing the spindle she was reduced to a perfect skeleton, but on this date a swelling, about an inch and a-half high and 8 inches in diameter, appeared suddenly about midway on the right flank, so low down as to be almost under the stomach, which for the first time gave an idea of the whereabouts of the spindle. This morning, the 10th September, the owner in passing his hand over the swelling felt the sharp point of the spindle projecting just a little out of the skin about 4 inches away from the anterior edge of the swelling.

The village goldsmith, with his wire-drawing tweezers, soon extracted and exposed the spindle to the gaze of the delighted villagers. It was brought to me this morning, and I examined it carefully. It was just 14½ inches in length and ½ of an inch in thickness in the middle, from which it tapered on both ends down to very fine points.

About 8 inches of the spindle was quite straight, and the other portion, on which the cotton had been rolled, was twisted, and bent by the action of her teeth. The cow is doing well.

W. E.

THE CALISAYA CONTROVERSY.

(To the Editor of the Planters' Gazette.)

SIR,—My time has been much occupied in the last two weeks in Quinological pursuits, and in returning your papers I send some brief notes. I am correcting, whilst passing through the press, my contribution to the subject, which will shortly be published by the Linnean Society. To this so corrected, I must refer you, in place of newspaper reports. I am availing myself of a visit of Mr. C. Ledger to this country to go carefully into the whole question with him and Mr. Holmes, the Curator of the Museum of the Pharmaceutical Society, and with others interested in the cultivation of Calisaya.

It will interest your readers to learn that Mr. Ledger is quite satisfied with my plants derived from the Yarrow Estate (Ceylon) as representing his true *Rojo* or red sort; resting his opinion on the characters I pointed out at the Linnean. He says that the beautiful richness of the foliage remains, especially in those parts of the tree which are least exposed. It is this sort to which the Indians attach so much value that they cross themselves when they meet with a tree of it and call it the *Tata* or "Father" tree believing (as I think not without reason) that it has a beneficial influence on all around, and that all be found "Calisaya" or true bark.

Mr. Ledger cannot tell what this word means, but Dr. Weddell, who spoke the Indian language, says (in his "Histoire," p. 31) that it means "the red sort," "Colli signifie, en effet, rouge, en langue Quichua, et *saya* parle un figuré, veut dire 'sorte' ou 'forme,' or (as I gather from Tschudi's German Dictionary of the language), *Cooli*, "the red of glowing embers." *Saya* "Stehen." Mr. Ledger fixed upon a slab of Calisaya in my possession nearly three-quarters of an inch in thickness as the true and highly prized *Rojo*. He tells me that Dr. Weddell had heard of the white flowers, and sought for them, but without success. To obtain this "red sort" has been the special aim of Mr. Ledger, and by special policy he was able to defeat the jealous tactics of the Indians, who boast that no one that obtains true seed shall leave the valleys alive. They either supply inferior qualities or destroy the germinating power. They laid wait for five days for Mr. Markham, who escaped through a Providential circumstance, and they poured boiling water on my friend Dr. Weddell's plants, who was profoundly affected by the outrage.

This *Rojo* is, then, the true *Ledgeriana*, as, in looking over my old letters, I fully recognize. Mr. Ledger sees it represented in my Plate IV. or the *Macho* form A. He does not see it in form B, or in the plant I have from Darjeeling which I think is probably the same B form. I have, in all, nine specimens of Java trees from Ledger's seed through the hands of M. Moens. There are different varieties in these, which Mr. L. does not recognize, but which are reproduced in specimens from British India. I should say, that his faithful Indian employed his own sons in gathering seed from fifty trees in different places, and the different collections got afterwards mixed together. The whole appeared to me to present Weddell's var. *microcarpa*.

Mr. Ledger entirely rejects my *Micranthus Calisayoides*; as also Dr. Trimen's plate. The colour of the changing leaves, he says, is exactly that which I copied from nature in the Calisaya Anglica, and the rich colouring of the leaves is perfectly given there, but the form of the leaves is, as above described in form A. When, as in the *C. Suocirubra*, the leaves turn this rich red colour, it is generally connected with rich colouring in the green of the leaves. This is a feature on which Ledger lays great stress, and it appears that many of the leaves assume this tint at the time of flowering. Hence the term *Colli* (Quichua) *Rojo*, (Spanish), *Rojo* (French).

Now, is this "red sort" a different specie from the Calisaya? It is not distinguished by the bark, for where the *Tata* trees are found (single amongst the *manchas* or patches) all the bark is good, owing, according to the Indians, to some connection with these chief trees. This is what I find in the specimens sent me by M. Moens from Java. Most are of equal quality to the true *Rojo*, some superior, others indicating, by proportions of Quinidine or of Cinchonidine, the influence of inferior pollen.

* The verb signifies to cover a fire with ashes so as to retain the glow.

The slab which Mr. Ledger pointed out as typical *Rojo* I have marked *Zamba*, a name belonging, as I thought, and Weddell confirmed this, to this var. *Microcarpa*.

I cannot make all this fit in with what is called "correct botanical description," which seem to be consistent with leaving out all allusion to the bark in the description of the Bark Tree; as in Bonpland's most confusing account of his *Couadames*. The Spanish botanists and Weddell were most particular to collect samples and carefully to describe the bark. I have approached the subject from the side of the bark, and consequently consider this the chief factor in the problem. I think practical cultivators will agree with me in this. My term "*Ledgeriana*" was meant to include all the bark of a certain rich quality grown in Java from Ledger's bag of seeds, and called such in trade. But the true *Ledgeriana* must be the *Rojo* of Ledger, and again I ask what is that? It is the form A of my Quinology, that is, the *Macho* form, distinguished, as Weddell shows (p. 31, Histoire) all such forms are by richer colouring (the purple of the under side, however, is accidental); and, as I think, by its furnishing prolific pollen needed to keep up the superior strain of these best qualities. Without this, they would degenerate, as in an analogous manner is the case with animals. The Indians, by long observation, are nearer the mark than the scientific botanists!

These are questions for practical cultivators. By a kind of reversal of the process above hinted, my gardener obtains for me *degenerate* cucumbers, i. e., without seed, and consequently sweeter, and devoid of the strong principle which disagrees with some persons. By careful fertilization, he keeps up the strain of my melons; and by artificial impregnation, requiring skill, he succeeds in growing beautiful pods of Vanilla, equal to the best in the market.

I would always have a sprinkling of *Tata* trees in my plantations of Calisaya, and should then count on having all of what the Indians call true Calisaya quality.

I remain, yours, &c.,
JOHN ELIOT HOWARD, F.R.S., F.L.S.

The Indian Agriculturist.

CALCUTTA, OCTOBER 1, 1883.

INDIGO.

MUCH has been said during the past twelve months about artificial indigo, and much about chemical and mechanical processes for augmenting the yield of the natural dye. Generally speaking, the former has been stigmatised by manufacturers and others concerned in the latter as at best but a poor imitation. They take the word artificial in its literal sense, and refuse to believe that artificial indigo is identical, chemically as well as physically, with the indigo of agriculture. The few who acknowledge it to be one and the same assert that its price must for a long time keep it without the pale of competition. It is useless to attempt to convince persons holding these views. They, naturally perhaps, do not wish to realise the truth. We, however, positively set it down, that artificial indigo stands exactly in the same relation to the indigo of agriculture, as does ice naturally formed in northern latitudes to that formed by means of chemicals in the east. Just as we can, by exploding the gases hydrogen and oxygen in certain proportions, form water, so can we bring together from various sources the elements of indigo, and resolve them into indigo. This position being impregnable, it is to be hoped that the disastrous season just closed will tend to open the eyes of those concerned, to the consequences of an advance in the home market of the artificial material. It is true that the processes at present followed in its manufacture are tedious and expensive; but it is reasonable to expect that, like most things owing their origin to the ingenuity of man, it will speedily be brought within the reach of all classes, a consummation, of course, anything but devoutly wished by those engaged in the manufacture of the natural dye—a consummation, however, which they are not altogether powerless to avert. No advance has been made either towards the comprehension of the thing itself,

* Le plus riche en Quinine de tous les Quinquinas dont on ait publié, jusqu'à ce jour, les analyses. — Bulletin de la Société Botanique de France, 9 Mars, 1885.

the superior variety may be found to thrive in the same neighbourhood. It is one of the most highly nitrogenous or towards an insight into processes the adoption of which would, for a time at least, effectually check its development, that is, by those most able to deal with them. It rarely happens that an individual influence or cause presents itself in an isolated form. The discovery of artificial indigo was followed by the utilization of a bye-product of aluminum manufacture, equal in all respects, except *softness of lustre* to indigo. The monopoly of this dye was purchased by a member of one of the largest firms of indigo brokers in London. This, it might be inferred, coming so fast after the more important discovery, would have roused manufacturers of and speculators in natural indigo, into action. These discoveries, together with reliable reports as to increased sales of indophenol, methylene blue, alizarin blue, and other by no means despicable substitutes for indigo, they have treated, if not with actual contempt, at least with the most glaring indifference. Another influence has now cropped up, which, taken with those which have gone before, point to considerable changes in the indigo industry of India. We are in a position to state that steps are at present being taken to cultivate and manufacture indigo on a very large scale in countries not very remote from India, and that certain *proved processes* guaranteeing from 50 to 100 per cent increase in yield, above the ordinary process of manufacture, will be adopted. These processes were offered for sale in Calcutta, and rejected on all sides, with the result, that competition has been set up of a kind not hitherto experienced, and on which we are not at present permitted to dwell, more than to say that such will be under trained Indian management, and that all the newest improvements with regard to machinery and culture will be adopted. We shall of course be debarred from using the patents alluded to in India, for it is most unlikely that the patentees will grant royalties under the circumstances stated—that is, to people whom it is their purpose to oppose. The out-look, therefore, from India is not at all pleasant in view of the drawbacks peculiar to climate, the gradual reduction of the artificial product at home, and the competition alluded to, with advantages *now* beyond our reach to be set up away from us, but sufficiently near to be felt. Our ultra-Indian competitors, from being able to manufacture cheaply, will doubtless establish the rates. They will sell 50, 60, and 70 per cent indigo at a profit, while we dispose of it at a sacrifice. It may be said that it will take a long time to overstock the market to such an extent as to necessitate reduction. So much the better for our ultra-Indian competitors. They will reap large profits, while we barely exist, and by the time that we begin to realise the fact that we have from the beginning avoided information most accessible, and refused processes most intelligible, the artificial product will be in full operation against us. We have said that we are not altogether powerless to avert this calamity. But we doubt very much whether it would improve matters were we to explain how, for we have come to the conclusion that the few speculators who at present rule the market are not so shortsighted as they appear. Contemplating, perhaps, early retirement. They say to themselves, "The devil take the hindmost." "Explain your patent improved processes to our successors." Whether this is fair to the manufacturers, who are in many cases financed and advised by them, is a question which they themselves must consider.

We can well understand that it would be much more satisfactory for those at present interested to go on in the old way; but as it is becoming widely known that not one of the multifarious blue dyes offered to the public as substitutes for indigo, can compare with such in exquisite softness of tint, it is to be expected that workers in science will leave no stone unturned to produce indigo at a price which will create an immediate and large demand. Our obvious duty, under the circumstances, is to obviate this necessity.

This we will not do by treating inventors with scorn, and driving them disgusted from the country. It seems almost beyond belief that in this City of Palaces, this nursery of merchant princes, the capital of a province identified with the indigo industry, there cannot be found a capitalist, or body of

capitalists, willing to launch a company to work patents of such high promise, say, as Michael's. "I don't believe in your chemicals!" is a frequent iteration of persons opposed to improved processes. The expression, it will be seen, is a hackneyed one. "You may get an increase," they say, "but the colour *must* be bad." This is the logic that science has to contend against. Quinine is obtained from cinchona bark, it is obtained from the bark by means of chemicals; *ergo*, it cannot be the same as the quinine dissolved out of the bark by water. The same might be said of hundreds of valuable drugs which have to be extracted by chemical means from the plants in which they are developed—drugs a thousand times more delicate than indigo. To make indigo, then, an exception, is simply to subordinate Western intellect to Asiatic fancy, or, as we have before hinted, it is purposely excepted. There is a consequence to which the collapse of the indigo industry will lead, which demands more than mere passing attention—*viz.* the abandonment of thousands of labourers whose interests are totally bound up in it. History shows that the sudden collapse of an industry of this magnitude must be followed by serious results. It will, therefore, be well if Government give a closer consideration to certain complications which may arise, in the event of our conjectures with regard to the future of indigo proving more dismal than we care to presage. What we are especially in want of at the present time, is that criticism of the improbable, barely probable, and possible, which our manufacturers themselves are so well able to advance. We look in vain for this. Pig-sticking and horse-racing are evidently more congenial pursuits. We are not of those who condemn sport—indeed, we should be the last to wish for any change in the present routine of an indigo-planter's life: but we do think that they should at times manifest some deeper interest in affairs pertaining to their vocation, ventilate their opinions and grievances, so that the true condition of things might be accurately judged, and the worst possible results anticipated. They have a journal specially representing their own interests, *The Indigo Planter's Gazette* elegantly got up, and well conducted. But it is a rare occurrence to see anything in the correspondence columns pertaining to indigo. Nothing points more strongly than this to the lack of interest exhibited by indigo-planters in their own affairs. For this reason, should calamity befall them, should this great staple take its place in the obituary of commercial products, scant sympathy will be shown them.

One year ago artificial indigo was not found in commerce in an isolated state, that is, in anything like the form of the indigo of agriculture. It was sold as a paste, called propiolic acid, and from this, was developed, on the fabrics to be dyed, pure indigo. A few months ago the Baden Chemical Company succeeded in producing a liquor of a deep yellow colour, from which, on exposure to the air, indigo separated out.

THE NAGPORE MODEL FARM REPORT.

THE two points that seem to call for most prominent notice in the Report on the Nagpore Model Farm for the year 1882-3, are the change of system and site, and the attempt to introduce Kachi cultivators from Cawnpore. Before dealing with either of these topics, we have a word or two to say regarding the various hands through which reports on purely agricultural matters pass. The Nagpore Model Farm Report is as good an example as any of what we mean. The Central Provinces has a Director of Agriculture who, we may suppose, is responsible for agricultural matters over which Government money is expended. The report of the farm is written by the person superintending the farm, and passed on to the Provincial Director of Agriculture. He in turn writes what amounts to a review of the report, and passes both on to the Secretary of the Chief Commissioner. The latter, in a letter to the Director of Agriculture, writes what is virtually a resolution on both documents, and the three deliverances are printed as Model Farm literature. We do not wish to question the wide knowledge and capacity of Indian Secretaries. There is scarcely any topic under the heavens or beyond them on

which they are not able to write a tolerably readable essay, and should the matter be unusually technical, their deficiency of knowledge may easily be covered under generalities and a cloud of words. No doubt it is in some respects highly desirable that the rulers of provinces should exercise supervision over all operations in which Government money is expended, but in the case of Agricultural Departments it seems to us that while the responsible officers of the Local Governments should in every case be consulted and hold the power of the purse, nevertheless, the Director-General of Agriculture is the person to whom the reports of the various provinces should be submitted. A general report, embodying what is valuable in provincial reports and passing in review the operations of each provincial department, would we, venture to think, be a valuable addition to the literature of Indian Agriculture. We are quite aware that the policy of the present Imperial Department of Agriculture is to leave a good deal, in fact, nearly everything, to provincial departments, and confine itself mainly to suggestions, to the collection of facts and information, and to the noting of useful experiments. A good deal no doubt can be said in favour of this, but in our estimation all matters agricultural, even to the reviewing of provincial reports, should be more or less under the control of a central office, ready at any moment to supply information of what is being done in every part of India in matters agricultural. There is another matter, we think, which calls for attention in connection with the Nagpore Model Farm. The net cost of the farm is less than that of the previous year by Rs. 2,115-5-7, the reduction being due to saving effected by placing the farm under Colonel Lugard's unpaid management, instead of retaining a European Superintendent. Colonel Lugard, the Deputy Commissioner, one would imagine, could find sufficient occupation in his district without taking on his shoulders the responsibility of superintending a Model Indian Farm. No doubt the persons who advised and confirmed such an arrangement are prepared to prove a hundred times over that it is the best of all possible arrangements financially, scientifically, governmentally, philosophically, and every other way; nevertheless, the non-official heathen lying in outer darkness will blaspheme and will not dance to the pipings of Directors of Agriculture or Secretaries of Chief Commissioners.

Turning to the matters noted at the opening of this article, we find the Director of Agriculture of the Central Provinces saying:—

"In the reports for the past eight years the unsuitability of the farm site for experimental agriculture has been often strongly insisted upon, and this opinion is corroborated by Colonel Lugard's experience. During the year under report, it was accordingly determined to discontinue Government farming altogether on the Model Farm site, and to limit agricultural experiments in future to a smaller, but much more favorably situated tract of land lying immediately south of the 'Maharaj Bagh.' 'Model' farming on a large scale will not be attempted in future, and all that will be aimed at is the careful conduct of experiments on a sufficiently large scale to render the results reliable. Experimental farming on this new site has already been started. Part of the area of the Model Farm has been disposed of by lease to cultivators. Part will be utilised as a sewage farm for Sitabuldi and the Civil station of Nagpore, and for this purpose a tract has been reserved of sufficient area to utilize the whole of the sewage and of the irrigation water available."

In this conclusion we heartily agree, and hope in future reports to see good results following from such sensible determinations. The attempt to introduce Kachi cultivators—is succinctly described by the Director:—

"Very little agricultural use is at present made of the sewage of Nagpore, and the income which the Municipality derives from it is quite insignificant. The Kunbi cultivators round the city are strongly prejudiced against using it, and are quite ignorant of the manner in which it can be used to best advantage. It was therefore determined in June 1882 to import some cultivators of the Kachi caste from Cawnpore, and endeavour to proselytise the Kunbis through their example.

Twelve of these men were accordingly brought down to Nagpore, and were at the outset entertained as paid labourers on a very liberal rate of salary. They promised exceedingly badly, and were very idle and discontented. In September the three most obstructive of the number were sent summarily back to Cawnpore, and the rest were induced to accept an arrangement under which their salary was reduced from Rs. 7 to Rs. 4, and in return for this they were given four acres of land rent-free for nine months, with the right to use, free of charge, the manure stored in the farm sewage pits. At the end of this period all salary was to cease, and the land was to be assessed to rent. The crops which they grew under these conditions were exceedingly good, and gave them handsome profits. Their salary has now been discontinued, and they have accepted 6 acres of land on a five-years' lease at a progressive rent, which has been fixed at Rs. 5 per acre in the first, and Rs. 15 in the fifth year. This is exclusive of water rate, which is charged for separately according to the amount used. A portion of the Sitabuldi sewage is stored in pits close to their fields, and they are allowed to use as much of it as they please, free of charge, Government undertaking to maintain the supply. It is too early yet to speak with confidence of the future of the scheme, but I am glad to be able to report that their example appears to be having the desired effect on the Kunbi cultivators. The latter have from the first shown great jealousy of the Kachis, and within the last two months three Kunbis have come forward with applications for land on similar terms. Two of these applications have been accepted, and the men are in possession of their land. It has been expressly stipulated that they are to use the sewage with their own hands, and not to employ *Bhungi* labourers. The result of their cultivation may be expected to yield some really trustworthy data as to the agricultural value of sewage, the best method of utilizing it, and as to the value of irrigation when used in conjunction with it. There can be no doubt whatever that lack of irrigation is the principal obstacle to the proper utilization of city sewage in these provinces, and it may be possible to demonstrate that the value of water when applied to a sewage farm is sufficiently high to render it profitable to incur a considerable outlay in bringing it on to the land."

REPORT OF THE GOVERNMENT BOTANICAL GARDENS AT SAHARUNPORE AND MUSSOORIE.

THE Report on the progress and condition of the Government Botanical Gardens at Saharunpore and Mussoorie, which has just come to hand, calls for a few remarks. The distribution of plants shows an increase of 35,688 over last year. The total weight of drugs has fallen off from 1,377lb. in 1881 to 616lb. 10oz. in the present year. The receipts were Rs. 7,095-9, as compared with Rs. 6,937 of last year. The net cost of the gardens to the State has increased from Rs. 19,871-15 to Rs. 21,919-2. This increase is mainly due to plants and seeds distributed gratis to soldiers' gardens and to an increase in salary to Mr. Gollan.

Perhaps the most important class of recent introductions to the gardens are the various kinds of plants that are especially adapted for growing on salt or sandy soils; of these the *Atriplex nummularia* has been distributed to Mr. Wilson at Awa and Mr. Impay at Cawnpore, and in both places has been found to thrive admirably on soil of the worst kind. A large quantity of seed has been sent for from Australia, and it may be the means of covering the now nearly useless stretches of usar in the Doab and elsewhere with a vegetation that will be of some use as a fodder for cattle, and of still more value in checking erosion, and gradually depositing a layer of humus over the barren salt. Besides this, the sand bush of South Africa, which flourishes in deserts and can survive a prolonged drought, may be found of use for the same purposes.

Mr. Bennett, the Director of Agriculture, N.-W.P. and Oudh, hopes that among food plants the soy bean may become a success. The existence of an inferior native congener in the lower ranges of the Himalayas encourages the expectation that

forms of food known, and should prove a valuable addition to the food supply of the country. The yields of imported cottons were fairly good. New Orleans gave 220lb., Upland Georgian 206lb., and other varieties 180lb. to the acre. In calculating the value of the crop, the bazaar price of the native varieties has been taken; but in the great cotton market of Cawnpore, the American realizes more than half as much again as the native fibre. The experiments made at Saharunpore confirm the results obtained on a much larger scale at the Cawnpore farm, and are chiefly valuable in showing that American cottons will thrive equally well in the different climate and soil of the former district. The coarse variety which was imported last year from the Garo Hills has not proved a success.

The following acclimatized and imported varieties of cotton were cultivated during the past year:—

| Acclimatized. | Imported. |
|------------------|---------------------|
| Egyptian. | Louisiana. |
| Garo Hills. | Louisiana Prolific. |
| Hingunghat. | Georgian. |
| Nankin. | Sea Island. |
| New Orleans. | Upland Georgian. |
| Tree Cotton. | |
| Upland Georgian. | |

As in past years, says the report, the acclimatized varieties of New Orleans and Upland Georgian gave the best return per acre. The first named variety produced 8 maunds 10 seers and the second 7 maunds 30 seers uncleaned cotton per acre. The value of the crop, calculated at 8 seers per rupee, is Rs. 41-4-0 and Rs. 38-12-0, respectively. The cost of production was about Rs. 24 per acre, which, deducted from the total, leaves a balance of Rs. 17-4-0 and Rs. 14-12-0 profit per acre. I have valued it at the rate obtainable in the bazaar for the common country cotton. It is of superior quality when compared with the latter, and I have no doubt would command a much higher price if produced in sufficiently large quantity.

The Egyptian, Hingunghat, Nankin, and Tree cotton produced on an average 6 maunds of uncleaned cotton per acre. If calculated at the same value as the New Orleans and Upland Georgian varieties, and deducting the same amount for cost of production, the balance of profit left would only amount to Rs. 6 per acre. Under more favourable circumstances these varieties, and also the two first named, are capable of producing heavier crops. The plot in which they were grown had been for some years previously occupied by rhea, which is known to be a gross feeder. The Garo Hills variety germinated very badly. It was received rather late for sowing in the previous season, and the pods then produced evidently did not contain many perfect seeds. Only 40 plants germinated and produced two seers of uncleaned cotton. This is not a large quantity for the number of plants; the yield, however, may improve when the plant becomes thoroughly acclimatized. The imported varieties gave a poor return, although grown under the same conditions as the acclimatized. They all germinated freely, but none of them grew to a height of more than twelve inches. They have all ripened, a few pods, and if the seed is properly developed may give better results next year. The fibre of the Sea Island is much superior to any of the acclimatized varieties we at present possess. If it can be acclimatized and made as productive as the New Orleans, it will be a decided acquisition. The Louisiana, Louisiana Prolific, Georgian, and Upland Georgian are all very much alike. The fibre of all four varieties is similar to that produced by the acclimatized New Orleans and Upland Georgian.

The following is Mr. Duthie's account of the silk-worm experiments:—

As the improvement of silk and the extension of this industry has lately been engaging the attention of the Government of India, I was induced to try a small experiment here in order to ascertain how far the climate of Saharunpore would prove suitable for rearing the silk-worms.

Two ounces of eggs were received about the middle of last February from Captain Murray, Dehra Dun. The first worms appeared on the 25th of that month, and the last were hatched

on the 20th of March. As they were all kept in the same temperature, such irregularity in hatching seems remarkable. The worms were at first fed solely on *Morus multicaulis*; but as the leaves of that variety of mulberry ran short, those of the common kind (*M. indica*) were given and were as eagerly devoured as the former. Leaves of *M. alba*, and of another variety with broad thin leaves, said to have been introduced from Kashmir, were also given, but the worms did not eat either of them so greedily as the two first-named. The total weight of leaves used amounted to 612lb. A less quantity would have sufficed if hot dry winds had not prevailed during the greater part of the period they were being fed. The leaves were often too hard and dry for the worms within half-an-hour after being supplied. The first cocoons were spun on the 23rd of March, and the last on the 23rd of April. The total number produced was 10,400, and their weight in a dry state was 9lb. 6oz. The following is Captain Murray's opinion on a small sample taken at random from this first batch of cocoons:— "I took your cocoons to the silk exhibition held here last Friday, to see whether they would come up to those raised in the Dun. All I can say is that, if at Saharunpore you can raise any quantity like those few sent to me, the people of the district have an industry to their hands. I do not say your cocoons are so good as those raised by my son, but they are very good indeed." Two pounds of the cocoons were reserved for eggs, and the remainder killed by exposure to the sun. The moths from the seed cocoons have produced their eggs, and as they are of the bivoltine variety of silk-moth, another batch of worms will soon be hatching. Until this second batch has been brought to the cocoon stage the experiment may be said to be only half finished. The amount expended on the experiment up to the period when all the cocoons had been formed was Rs. 20. This amount is really the pay of the men employed in bringing leaves and tending the worms. The same amount of money would have sufficed for an experiment on a much larger scale. Mr. Gollan has personally supervised the experiment from the commencement; all credit is therefore due to him (says Mr. Duthie) for its ultimate success.

The possession of a new site for the Gardens at Arnighat has now been obtained with a cultivable area of 30 acres on a projecting plateau of a hill-side 5,000 above the sea, and the work of removing all that is worth moving is now being taken in hand.

EDITORIAL NOTES.

A CORRESPONDENT writes to us pointing out that the derivation of *Fijurat* from two Hindi words given last month in the leading article on Agricultural Banks is "as fanciful as it is incorrect." We shall be glad if our correspondent will furnish us with the correct derivation.

A PREMIUM of 6d. per dozen has, it appears, been placed upon sparrows' heads by the Government of South Australia, acting on the advice of a Commission specially appointed to inquire into the "sparrow question," while the somewhat disproportionate sum of 2s. 6d. per 100 is offered for the eggs of the bird.

THE committee engaged in the organisation of the Austro-German Exhibition of 1885 recently, it seems, addressed a petition to Prince Bismarck, asking for the support of the Imperial Government. In this document reference was made to the Austro-German Exhibition of Art and Industry, held at Munich in 1876, and to the opinion then generally formed, that the repetition of such displays in important cities would be of undoubted advantage. An interval of six to eight years was then spoken of as being the most suitable, but in this instance a longer delay has been inevitable, as Berlin was selected for the next Exhibition, and up to the present time that city has not possessed a fire-proof building of a suitable character. This difficulty having been removed by the erection of the Hygienic Exhibition, the suggestion was made in the document referred to, that this building should be utilised for the purpose indicated. According to the most recent

information published upon the subject in the German press, the proposal has met with the approval of the Chancellor, and of the Imperial Court. It is stated in the *Cologne Gazette* that the municipality of Berlin will, in all probability, take over or hire the principal building of the present Exhibition. In this case there would be held, in 1885, the proposed exhibition of industrial art; in 1887, an international trade exhibition; and in 1888 an electro-technical display. It had been at one time proposed to include France in the Exhibition of 1885, but this idea has been abandoned.

From a summary of the agricultural returns of Great Britain for the present year, lately issued by the Agricultural Department of the Privy Council, it appears that the acreage under the five main crops are—Wheat, 2,813,147; barley, 2,391,984; oats, 2,975,377; potatoes, 543,455; and hops, 68,027. As compared with the returns for 1882, there is a decrease to the extent of 390,813 acres in the case of wheat, but an enlarged acreage in the case of the other four crops; thus, of barley the increase amounts to 36,715 acres; oats, 141,512 acres; potatoes, 2,891 acres; and hops, 2,408 acres.

TANNING TEXTILE FABRICS.—M. Piron, a Belgian, has invented a process for tanning textile fabrics which renders them waterproof, and at the same time, it is said, proof against decay, while their suppleness is not diminished, and their weight not appreciably increased. Arguing from the high state of preservation in which the bands which surround the heads of Egyptian mummies are found to this day, and which are impregnated with a kind of resin, M. Piron had recourse to the substance extracted from birch bark, and which is now used to perfume Russia leather. When the fine white bark of the birch tree is distilled, it yields a light oil, nearly a fourth part of which consists of the special phenol, or carbolic acid, which gives the well-known odour to Russia leather. It is now found that the residue, or green tar of the birch, which is obtained from *Kostroma*, yields neither acid, nor alkaloid, and it forms, with alcohol, a solution of great fluidity, which, however, when once dried, is unacted upon by alcohol. It is this substance, which will unite with the most brilliant colours, that is used by M. Piron for treating textile fabrics. Not only does it fill the capillary vessels, but it also coats them with a varnish of great elasticity, which is unattackable by acids and sea water, while it also stands great changes of temperature. The aromatic odour of articles thus treated drives away insects; there is no space for microscopic vegetation, and neither air nor water can penetrate into the tissues. This process is applicable to all vegetable products, such as sail-cloth, cordage, blinds, and awnings.

THE current number of the *Jamaica Handbook* contains valuable information upon the trade and production of the island, from which it is evident, says the *Planter's Gazette*, not merely that European enterprise is extending in various new directions, such as cinchona, cocoa, &c., whilst the exports of sugar and rum last year were larger than for nearly forty years previously, but that the economical condition of the negroes forming the bulk of the population has also greatly improved. The total exports for the past financial year amount in value to over a million-and-half sterling, being an increase of more than £370,000 (we give round figures throughout) on the previous year, and of £205,000 on the average of the five years preceding. On the other hand, the imports have decreased by £70,000, and as this decrease was mainly due to the largely-increased production of ground provisions and other necessities grown by the native population, it must really be counted as so much gain on the whole to the people—in other words, to the negroes themselves, who form the practical working body of the colony. If they have paid so much the less to outsiders for food, it is because they have raised so much the more themselves for home consumption. When we come to examine the details of the figures, the results are still more striking. The industries peculiarly affected by the free black on his own account show a great general increase. True, last year was a bad one, owing to drought for the coffee crop, the principal

stand-by of the industrious hill negroes; and the exports fell to 68,000 cwt. valued at £133,000 as against 87,000 cwt. (£221,000) in the preceding year, and 98,000 cwt. (£340,000) in 1879. This is a serious loss, but the fact that in spite of it the total exports was more than maintained is a very promising one for the future of the colony. At present the industries are becoming more varied, and a loss in one direction may be more than counterbalanced by a gain in another. The most noticeable of all the features in the report is the immense and steady increase in the small negro's business *par excellence*, the fruit trade with America. In 1867 this consisted of a few bunches of bananas and barrels of oranges valued at £725; last year the export of oranges alone had risen to 35 millions, and the value of the trade was £124,000. For a small country like Jamaica, with only half-a-million of inhabitants, this is a very large sum indeed; but what makes it all the more important is the fact that the fruit is almost entirely grown by the small negro peasant proprietor, and that the money thus goes directly into the hands of the people. The total number of holdings of land in the island is fifty-two thousand, of which nearly ten thousand are less than one acre, and twenty-six thousand are between one and three acres; and the proportion of these small holdings under cultivation is far and away greater than the large estates, a vast part of which still remains in wild land. All these facts go to confirm the belief, already held by most of those who know the West Indian negro personally, that the small proprietors are steadily, though slowly, progressing in habits of industry, thrift, and civilization.

THERE is no special mode of making butter (writes Professor Arnold) which is better under all circumstances than every other. What is best for one may not be best for another. The method pursued by an inquiring friend who lowers his milk in deep and narrow vessels into water in his well with a temperature of 50 degs. for thirty-six hours, may be, and probably is, best for him with a small dairy, since he makes an article that brings 4 or 5 cents a pound above other dairy butter in his neighbourhood, but such a practice could not be followed in a large creamery with any convenience or profit; besides, everybody cannot provide himself with such a well. The very finest butter is made by setting shallow in a pure and only moderately cool air; yet this method is now best for general use, because it calls for too much room, too much labour, and too much time and expense, to be acceptable or profitable for those who have much milk to handle. Though the butter might be very choice, it would be too expensive to compete with butter nearly as good, but made with one-quarter the labour and expense, and in half the time. The Elgin creamery buys the milk of 800 to 1,000 cows from large dairies near the city. The best mode in such a case is to set the milk in large vats and cool vigorously with iced water to hurry the separation of the cream, and do it with the least expense; but in new and sparsely-settled localities, it is better to cream the milk at the farm in small vessels with only such refrigeration as the farm affords, and to send only the cream to the factory. Though sudden changes in milk, cream, or butter are not conducive to the highest quality or longest keeping, yet rapid refrigeration, as a rule, brings the best practical results, because it makes a more perfect separation of cream than slow cooling and saves time and expense in working, and thus reduces cost. For those who relish the peculiarly fresh acid taste of a little buttermilk in their butter, unwashed butter will be preferred while it is new. As soon, however, as the buttermilk which adheres to it has had time to change—which it will do in about forty-eight hours in warm weather—its fresh taste disappears, and it begins at first to be stale, then strong, and finally rancid, and decidedly objectionable. If the working is so thorough as to practically remove all of the buttermilk, the increased amount of violence breaks the grain of the butter, and this is about as bad as buttermilk to injure its keeping, so that worked butter is short lived according to the amount of working done to it, or the quantity of buttermilk left in it. Butter which is well washed in good water, especially when it is gathered in pellets or granules instead of in a mass, has no taste of buttermilk, and for this reason those

who prefer that flavour do not admire it so much as unwashed butter. Nine out of ten persons, however, prefer the pure, distinct, and full flavour of butter unadulterated with buttermilk or disguised with excessive salt, and this flavour is obtained only by washing every particle of buttermilk from it, and avoiding the working which must follow when washing is omitted.

A Cotton exposition on a large scale is being organised in the Southern States of America. The committee's prize-list exceeds 5,000 dollars, and it is anticipated that this amount will be largely added to in premiums offered by local dealers. The highest prize offered is 1,000 dollars, for the best bale, long staple (first); and the lowest, 50 dollars, for the best twenty stalks of cotton of the second quality.

Most farmers have great ideas of creating an improved cow by crossing one breed with another, such as the Jersey with the Ayrshire or Holstein. These violent crosses are opposed to all the principles of breeding, and the great prepotency of the two animals used for the cross are put at war with one another. This creates the greatest uncertainty as to results, and there is sure to be a want of uniformity in the offspring. It is better to grade than to cross, that is, use a thoroughbred bull of your favorite breed on a native cow. This native will be found to respond kindly to this treatment, and the offspring will follow strongly the prepotency of the bull.—*American Dairyman*.

SOME comparatively recent investigations of Professor Forbes, the State Entomologist of Illinois, and published in the "Science" column of the *New York Independent*, are exceedingly instructive. He selected an orchard which for six years had been stripped by the canker worms. He shot a considerable number of birds therein for two successive years, on May 24, 1881, and May 20, 1882, representing nearly all the kinds seen in the orchards, made full notes of the relative abundance of the species, examined carefully the contents of all the stomachs obtained, and tabulated the results. It appeared that the robin and six other species of the family had eaten no vegetable food, 96 per cent consisting of insects, of which 16 per cent was canker worms and only 4 per cent insectivorous beetles. The blue-bird ate 12 per cent of canker worms; the house-wren 20 per cent; fourteen warblers ate 75 per cent of canker worms; thirty cedar wax-wings destroyed 2,000 canker worms a day or 90,000 for the month during which the worm is exposed; and forty-seven finches, or seed and grain eaters, ate 98 per cent of insects, of which 40 per cent was canker worms. From these observations the author concludes that birds of the most varied character and habits, migrate and resident, of all sizes, from the tiny wren to the blue-jay, birds of the forest, garden and meadow, those of arboreal and those of terrestrial habit, were either attracted or detained here by the bountiful supply of insect food, and were feeding freely upon the species most abundant. That 35 per cent of the food of all the birds congregated in this orchard should have consisted of a single species of insect is a fact so extraordinary that its meaning cannot be mistaken. Whatever power the birds of this vicinity possessed, as checks upon destructive irruptions of insect life, was being largely exerted here to restore the broken balance of organic nature.

THE fundamental principles of reproduction [N. Y. Agricultural Experiment Station, Geneva, N. Y., July 7, 1883] seem alike in the animal and vegetable kingdom. In both, the mystery of life; in both, accretion through cell multiplication; in both, changes of form as arising from immediate heredity and as governed by environment. In our domesticated plants as in our domesticated animals, we have the male and the female element of varying potency whose union is productive of the new individual. Both classes are alike influenced by the conditions described under the term selection. We can, hence, speak of breeding the plant as legitimately as we can speak of breeding the animal. We may also use the term, pedigree, as applied to the improved forms of animals. As in our domesticated animals, improvement is brought about

through the systematic mating and selection which constitute pedigree, so the same system in our domesticated plants will avail to produce an improvement which may be described in the same terms. If a pedigreed animal is superior in value on account of the conditions which allow this term to apply, then a pedigreed plant must necessarily possess superior value over the plant which has been developed only through unsystematic effort. As the recognition of the value of systematic effort in improvement has differentiated the pursuit of animal breeding, and has constituted a class of men called breeders, so seed-growers should be likewise differentiated into a class called seed-breeders. Seed-breeding is already beginning to be, and soon must become, of importance as a farm or garden pursuit.

In gardening we have many illustrations of seed-breeding in the production of new forms of vegetables, secured through hybridization and careful selection, as also in the system called "rogueing," which consists in the removal from plants designed for seed purposes of all the plants which are untrue to the form desired. In agriculture we have fewer illustrations, and the farmer has applied less discrimination to his field produce than the gardener has to his small but more intensely cultivated garden. We have, however, a few illustrations in agriculture of what may be accomplished through the selection of seed under that uniformity of idea which is described as seed-breeding. In 1857, Major Hallet, of Brighton, England, commenced his experiments on wheat, selecting his seed from the quality of the plant produced, his standard embracing hardiness, truthness to type, quality of sample, productiveness, power of tillering, stiffness and toughness of straw and earliness of ripening. The results obtained may be expressed in the following table:

| Grains in original ear. | Kind of Wheat. | Grains in improved ear. |
|-------------------------|------------------------------------|-------------------------|
| 45 | Original red, commenced in 1857 .. | 123 |
| 60 | Hunter's White, " " 1861... | 124 |
| 80 | Victoria White, " " 1862... | 114 |
| 32 | Golden Drop, " " 1864... | 96 |

We have here an illustration of what has been obtained in the effort to increase the prolificacy of the plant, and this gain in prolificacy has also been attended by a gain in the size of the kernels. The amount of crop raised, or prolificacy of the plant under circumstances of field seeding also, if reports are to be trusted, offer parallel results; the increase of yield by the use of Hallet's seed in various countries in the world being reported as between two and three times the average crop from other varieties.

In the case of the Waushakum corn, the selection being made by castrating the barren stalks for two years in succession, the seed saved being not from the most prolific stalks that were left, but merely of the perfect ears, raised the average crop from about 45 bushels to 80 bushels to the acre.

Although the Station has not as yet had time to do much work in this direction, yet a beginning has been already made. On account of the importance of these facts relating to seed, we are disposed to quote the conclusions gained by Major Hallet, which read as follows:

1. Every fully developed plant of a cereal presents an ear superior in productive power to any of the rest on that plant.
2. Every such plant contains one grain which, upon trial, proves more productive than any other.
3. The best grain on a given plant is found in the best ear.
4. The superior vigor of this grain is transmissible, in different degrees, to its progeny.
5. By repeated careful selections the superiority is accumulated.
6. The improvement, which is at first rapid, gradually after a long series of years is diminished in amount, and eventually so far arrested that practically a limit to improvement in the desired quality is reached.
7. By still continuing to select, the improvement is maintained, and practically a fixed type is the result.

An account of Major Hallet's process may be found in *Popular Science Monthly* for July 1882.

So far as the Station work has gone, these claims of Major Hallet have received confirmation. It is particularly noticeable

able that when each kernel of the ear of wheat is planted by itself, one kernel has invariably proved far more productive than any other one, not *per gradum*, but *per saltum*, i. e. not regularly, but at a jump.—EL LEWIS STURTEVANT, Director.

I PLANTED a peach orchard, writes M. Siroy, of the Society of Horticulture, and the trees grew well and strongly. They had just commenced to bud when they were invaded by the *circulio* (*pilyon*), which insects were followed, as frequently happens, by ants. Having cut some tomatoes, the idea occurred that by placing some of the leaves around the trunks and branches of the peach trees, I might preserve them from the rays of the sun, which are very powerful. My surprise was great upon the following day to find my trees entirely free from their enemies, not one remaining, except here and there where a curled leaf prevented the tomato from exercising its influence. These leaves I carefully unrolled, placing upon them fresh ones from the tomato vine, with the result of banishing the last insect and enabling the trees to grow with luxuriance. Wishing to carry still further my experiment, I steeped in water some leaves of the tomato, and sprinkled with this infusion other plants, roses and oranges. In two days these were also free from the innumerable insects which covered them, and I felt sure that had I used the same means with my melon patch I should have met with the same result. I therefore deem it a duty I owe to the Society of Horticulture to make known this singular and useful property of the tomato leaves, which I discovered by the merest accident.

ALTHOUGH, says a contemporary, the teak forests of Upper Burmah are a source of wealth which for another generation at least will always bring in a handsome revenue, even if worked in the wasteful and extravagant manner which characterises most of the financial experiments of that country, they must come to an end in time, for no steps are taken in Upper Burmah to reproduce them. The mineral resources of Upper Burmah are known to be great, but these also are sadly neglected. The rich soil and the excellent climate should make agriculture what it has never yet been, the real source of the wealth of both people and Government. Wheat of an excellent description grows near Sagine, and two crops a year can be had with very little trouble. But few people care to cultivate anything beyond small patches yielding them from 20 to 30 baskets. If any one tried agriculture on an extended scale, he would at once be a marked man, and officials from the highest to the lowest would look upon him as a fit object for squeezing. Under such a rule it is hardly surprising that a soil which seems to "blossom at a touch" is often altogether neglected, and that people, who do not know if they will be allowed to reap, show a supreme indifference to the preliminary operations of ploughing and sowing. The Burman plough used in our own rice-fields is not a very scientific instrument, but it goes very much deeper into the soil than the one used in Upper Burmah, and yet even with their primitive implements wheat grows to profusion wherever it is planted. Upper Burmah might not only supply all our needs in this article, and render us independent of Indian supplies, but might export that grain to Europe, where a constant and remunerative market would always be met with. It is to be regretted that the more enlightened of the Burmese ministers do not awake to the advantages to be derived from extending wheat cultivation in their country, and imbuing agriculturists with the required faith in the stability and honesty of the present rule, which would result in improving the prosperity of the people and of the whole country.

The following resolution appears in the *Gazette of India* :—

"A frequent objection to the salt-tax in this country is that it makes salt so dear that the people cannot afford to give it to cattle in quantities sufficient for the health of their stock. In several European countries where salt is subject to a heavy duty, means have been found for supplying owners of stock with cheap salt for the use of their cattle and sheep. Without attempting to prejudge the case in any way, and without committing the Government beforehand to any pledges which it may be found impossible or inexpedient to fulfil, it may be

admitted that in India, where the bulk of the population is dependent on agriculture, it would be a distinct gain to be able to issue cheap salt for cattle, and the question of meeting this necessity in a way compatible with the safety of the salt revenue has more than once engaged the attention of the Government of India. On the last occasion on which the question was taken into consideration, it was suggested that the object aimed at would be secured if a process could be discovered by which salt could be rendered so unfit for human consumption that its restoration to an edible condition would be neither easy nor cheap, while it would still remain suitable for use by cattle. This suggestion commended itself to the Government of India, for, if this could be done, salt could safely be issued for stock at a comparatively cheap rate without coming into competition with salt intended for human consumption. Experiments for denaturalising salt were accordingly undertaken in Bengal and the Punjab, details of the processes used in Germany and France having been obtained through the Secretary of State. The experiments were a failure, in so far that they did not satisfy the main condition that the restoration of the medicated salt could not be cheaply and easily effected, while the German and other processes were found either unsuitable or otherwise objectionable in this country. The problem of issuing salt for cattle in a form which will not endanger the public revenue, therefore, still remains unsolved. The Governor-General in Council has again had the question under his consideration, in connection with a process devised by a private individual, and submitted for trial to the Commissioner of Northern India Salt Revenue. This process, like those previously tested by Government officers, has not given satisfactory results in practice. But his Excellency in Council is inclined to think, on perusal of the papers read in the preamble, that the experiments as yet made have not been as wide or exhaustive as the importance of the subject demands. If any satisfactory method could be devised which fully met the requirements of the case, a great boon would be conferred on the country, and it is hoped that a process may yet be discovered which, if not satisfying all the conditions hitherto prescribed, may yet be sufficient for all practical purposes. His Excellency in Council accordingly requests that the Local Governments will be good enough to arrange with their chemical analysts, or with any other thoroughly skilled and competent officer, for the commencement of systematic and careful experiments in the direction indicated. The officer selected should be furnished with a complete copy of the papers containing the details and results of all the attempts already made, and the results of the experiments made under these instructions should be communicated to the Government of India. If any private person should wish to take up the enquiry, the Government will be glad to furnish him, on application, with copies of the correspondence read in the preamble to this Resolution."

THE discovery of "Kairin," a quality latent in coal tar, which resembles that of quinine, says the *Madras Mail*, is likely to prove a blessing to mankind, should further experience confirm the result attained by careful experiments up to the present time. It had been known for some time past that the plants brought to India by Mr. Clements Markham belonged to an inferior species of cinchona, and are comparatively valueless. Useful alkaloids, no doubt, can be extracted from them, tinged, as it were, by a small amount of the virtues of true quinine, and it is possible that a febrifuge may be obtained sufficiently powerful to act upon the easily affected constitutions of the native population. But Europeans require a more potent principle to counteract the fury of fever. This febrifuge, which General Richard Strachey has taken under his especial patronage, is the utmost that science can extract from the immense plantations at Darjeeling. The Nilghiri trees must be classed under a different category. For the most part they are grown from Dutch seed, and are descended from the legitimate quinine-producing cinchona of South America. It is stated, however, that the process of extraction demands the utmost nicety of manipulation, and that native assistants have failed to give satisfaction even in the preparation of the milder febrifuge.

They could not be trusted to work by themselves, but had to be closely superintended through every stage of the operation. There is some talk, we believe, of making one more vigorous attempt to establish in Calcutta a thoroughly organized laboratory for the manufacture of febrifuge, abandoning all ambitious hopes of supplying the European garrison with Indian quinine as well as with Indian beer. The project of introducing the cinchona cultivation into Guatemala will create a formidable though beneficial rivalry. So long as quinine is obtainable at a price that will render its application universal, we must not look too closely to the quarter whence relief comes to the sick and suffering, though we may be pardoned a regret that such an unfortunate blunder was committed by Mr. Markham. At the same time, it appears to us a very short-sighted economy to maintain the Darjeeling plantations at a great cost for such little purpose, when, by the courageous expenditure of a certain sum of money, the true cinchona might be brought in to supplant its bastard brother. The real objection, we fancy, may be traced to a natural, if weak-minded, reluctance to acknowledge an error of judgment. Instead, however, of wasting time and money on the production of an inefficacious febrifuge, it would be far wiser to get rid of the Darjeeling plantations altogether, and to begin afresh with good Dutch seed, and with young plants from the Nilgiris. The Agricultural Department must have been nodding not to have taken up this matter heartily, and pressed it upon the earnest attention of the Government. The introduction of the true cinchona would be a far more valuable boon to "the bulk of the people" than the abolition of anomalies and the worship of the abstract."

THE following letter of Surgeon-General Balfour to the Under-Secretary of State for India has been communicated by the writer to the *Journal of the Society of Arts* :—

SIR,—During the bygone nine years, the quantities of poppy seeds exported from India have been on the increase, giving an outlet to a product which was formerly only locally used, and employing a considerable amount of tonnage.

I beg to place on the margin the countries to which it was shipped in the year 1881-2, and it would be of value to India, and to the mercantile and manufacturing communities of Europe, if information could be obtained as to the purposes for which, in France and the United Kingdom, such large quantities are utilised. In all probability it is pressed for the oil, which may be used as a substitute for olive oil.

It has been a subject of inquiry by Deputy-Surgeon-General Day, with myself, as to what oils are used for the sardines of the Mediterranean, in order that he might be able to recommend the same for the pilchard trade.—I have the honour to be, Sir, your obedient servant,

EDWARD BALFOUR.

Sir Louis Mallet, in his answer to Surgeon-General Balfour, enclosed a letter from the Board of Trade, signed by Mr. Giffen, containing the following particulars :—"The seeds in question are classified in the Import List amongst the

unnumerated seeds from which oil is expressed, and the Board of Trade have no information as to the uses to which they are applied. It appears, however, from a communication which has been received from Mr. Dyer, the Assistant Director of the Royal Botanical Gardens at Kew, that these seeds yield about 50 per cent of a very valuable oil, which is easily decolorised, dries well, and remains fluid to a low temperature, and it is understood that this oil has long been recommended as a substitute for olive oil."

A WRITER in the *Scientific American* states that, within 500 miles of New York city, there is a large section of country, comprising from 12,000 to 14,000 square miles, which, for the quality and variety of its minerals, is in all probability the richest and most interesting mineral country in the world, and one not surpassed by Saxony, in Europe. This remarkable section lies on the borders of Kentucky, Tennessee, North Carolina, and West Virginia. Seventeen counties of Virginia are included in it, and to these may be added Ashe, Alleghany, and Wantaga counties in North Carolina, which form an integral part of the same geological formation, and contain the same kind of minerals. In this section are to be found gold, silver, copper, lead, zinc, nickel, iron, manganese, plumbago, arsenic, antimony, limestone, gypsum, salt, barytes, kaolin, feldspar, soapstone, fireclay, asbestos, talc, mica, amber, millstone grit, marble, sandstone, granite, syonite, and many of the minor minerals useful in arts and manufactures. Besides this, the country is finely timbered, from the valleys to the mountain tops, with white oak, walnut, maple, tulip-tree, bass-wood, hickory, cherry, chestnut, buckeye, cucumber-tree, and other oaks, dogwood, white pine, black pine, spruce cedar, and many other useful and valuable woods. It is also a fine agricultural district.

THE great and growing increase in the consumption of paper, and the corresponding scarcity of rags, naturally cause attention to be turned to substances suitable for the paper manufacturer. Already the alfa and the ramie have been pressed into his service; and the same country which produces these, viz., Algeria, also affords another plant which, while being useful for this purpose, is, at the same time, a great enemy to the agriculturist. This is the dwarf palm, the fibrous properties of which have long been known to the Arabs, while they have been unable to turn them to account. A Frenchman, M. Reynaud, has found means for utilising the whole plant, except the roots, which serve for firing. Every part, from the stalk to the top-most leaves, is transformed into fibre of excellent quality, and it makes no difference if the plants have been pulled up several years previously. The plants are placed in a kind of cage, which is immersed in a boiler filled with a special lye, and heated. The substance being thus retted, becomes soft, so that the fibre may be readily separated. It is withdrawn from the bath, and drained, the lye being saved for use over again. It is then passed between rollers, while at the same time being made cold by quantities of water. The number of rollings, rinsings, and combings depend upon the degree of fineness required. At last, the product is allowed to fall into a receptacle containing pure water, whence it is withdrawn to be tied up in bundles for transport. The vegetable hair which may also be obtained from this plant is finer and more tenacious than any other known; it readily takes all the ordinary dyes, even without being bleached. As the whole of the tannin which it contains is not extracted, this plant is not liable to decay, while it is, at the same time, antiseptic, on account of its aromatic odour, and to some extent impermeable by water.

THE process of turning straw into paper from the raw material to rolls and sheets is an interesting one. Beginning in the upper part, the rye and oat straw hoisted by a fork, after being cut, is carried into a large cylinder. In this, the cut straw is cooked by steam, and mixed with chemicals, which are drawn from large tanks. From the digester the

cooked straw is taken to the bleaching machines, where the cooked mass is reduced to fine pulp, and from these it is taken to the beating engines to draw out the fibre, so that the stock will "web." After this process it is emptied into stuff chests and kept stirred by an "agitator." The pulp now for printing paper looks like milk and water, and for wrapping paper like thick mud, and of whatever colour desired; and it is ready for the paper-making machine." A floating cylinder in each tank takes up the pulp, conveys it on a felt carrier, where it passes through rollers weighing a thousand pounds, which presses out the water. It is now a sheet, and passes round eight drying cylinders four feet long and three feet in diameter, heated by steam. Next it goes through two sets of heavy thousand-pound rollers, and afterwards round a set of seven solid chilled rollers a foot in diameter. The paper is finished and passes to the cutter, where it is cut into sheets and packed in bales. By a new process it is expected to utilize flax straw, which has hitherto gone to waste.

TABLE napkins are regularly supplied at the cheap dining-rooms of Berlin. The napkins are of tissue paper, with a coloured ornamental border—not only because paper is cheaper than diaper, but as a protection against pilfering. Indeed so common are paper table napkins at Berlin that the manufacturers advertise them regularly in all the newspapers at 9s. per thousand, being about nine or ten a penny.

A new kind of matting or carpet for covering floors, says a contemporary, is composed of a fabric woven or knit from strands or threads of paper in such a manner that when, laid upon a floor, it will serve all the purposes of ordinary straw matting or textile carpets, and can be cleansed by washing when such becomes necessary or desirable.

Any kind of strong paper is taken and cut or formed into strips of the required or suitable size, and then twisted or spun into strands or threads. If a fine texture is desired, the strips are made smaller than where a coarse texture is preferred; but in either event the twisted or spun strands or threads are woven or knit into a fabric by any of the well-known methods practised in weaving or knitting textile material. Before or after the paper strands or threads are woven or knit into the matting or carpet, the paper may be rendered waterproof by saturation or impregnation with any known waterproofing material; or it may be otherwise chemically treated in order to strengthen it, and permit the use of water or other cleansing fluid in washing the floor covering when desired to free it from dirt or stains, and it may also be treated with carbolic acid or other material to prevent the ravages of insects.

If the strips of paper are properly and tightly twisted or spun into strands or threads and closely woven or knit, the fabric can be subjected to a moderate amount of washing without liability to injury. The strips of paper may be for mod very narrow and spun or twisted with strands of yarn: or the twisted paper strands may be woven or knit with some suitable animal or vegetable matter, the strips of twisted paper forming the warp or the woof, and the animal or vegetable matter forming the warp or the woof, as desired.

Paper strands or threads produced from differently-coloured paper, produce a variety of designs in the fabric during the process of weaving or knitting, as well as the various designs that are produced in ordinary tapestry; and the fabric can be woven or knit into any determined dimensions to be fitted to the floor of an apartment, so that the floor covering will be in a single piece.

Paper produced from what is known as the "palmetto-leaf" is preferred for this use as it is strong and durable; but it is obvious that paper produced from other substances can be used.

There is now every prospect, it seems, of excellent crops throughout the Canadian North-West. In Ontario the hay crop is the largest for the past twenty years, and the hay is now selling in Ottawa Valley for £1 12s. per ton. The grain crops in Ontario are not so abundant, but there is every probability that better prices will be paid than last year.

At the Royal Show at York, a new method was shown of utilizing skim milk. Mr. Ahlborn, of Hildesheim, Germany, at his model dairy made what he calls "sparkling milk," and which is neither less nor more than soda milk or aerated milk. It is skim milk impregnated with carbonic acid gas, in exactly the same manner as water in the manufacture of soda-water, and is forced into similar bottles, corked and wired down, and is then ready for sale. It will keep an indefinite period; one bottle was opened that had been made 17 weeks previously, and which was quite fresh and good, and as frisky as possible. It is a very takeable beverage, and was quite as refreshing to a thirsty soul as soda-water, with the additional advantage of being distinctly nutritious. The cost of making it is very small, and it could easily be sold as cheaply as soda-water. The price of the machine for making it is £40—possibly smaller sizes might be got—and the same machine will make aerated drinks of any kind.

We are all taught (says the *North British Agriculturist*) that by reason of the inclination of the earth's axis, the several seasons happen at different times in different portions of our globe, so that seed-times and harvests do not correspond in the various zones. But probably few persons realize that if all the harvest periods of the world were grouped together, they would be found to occupy altogether more than three-fourths of the whole year. As a fact, leaving out of sight altogether the equatorial and neighbouring regions, in which different seasons are actually contemporaneous, there are perhaps only two months out of the twelve in which the harvest is not being actually gathered somewhere on the face of the earth. Thus, in the greater part of Chili, portions of the Argentine Republic, Australia, and New Zealand, January is the harvest month. It begins in February in the East Indies, going on into March as we come North. Mexico, Egypt, Persia, and Syria reap in April; while Japan, China, Northern Asia Minor, Tunis, Algiers, and Morocco, and also Texas, do so in May. California, Spain, Portugal, Italy, Sicily, Greece, and some of the southern departments of France, gather the harvest in June. July is the harvest month for the greater part of France, for Austria, South Russia, and the greater part of the United States of America; Germany reaps in August with England, Belgium, the Netherlands, part of Russia, Denmark, part of Canada, and the North-Eastern States of America; September is the time for Scotland, the greater part of Canada, Sweden, Norway, and the Northern Midlands of Russia; while the harvest drags on slowly throughout October in the most northern parts of Russia and the Scandinavian Peninsula. It would thus seem that November and December are the only months which have not a place in the harvest calendar of the world.

THE frequency of thunderstorms in Switzerland this summer has afforded Professor Colladon, of Geneva, a great authority on electricity and meteorology, ample opportunity of continuing his observations on the effect of lightning on trees and vegetation generally. He has ascertained that when lightning strikes a tree it leaves very few marks of its passage on the upper part and middle of the trunk—a peculiarity which he ascribes to the fact of those parts being more impregnated with sugar, a good conductor, than the lower part. As the electric fluid descends to the neighbourhood of the heavier branches, where there is less saccharine matter, it tears open the bark, and in many instances shivers the tree. It is no uncommon thing to find the lower part of a tree literally cut by the lightning, while the upper portion and the higher branches seem to have suffered hardly at all. Oaks, however, would appear to present an exception to this rule, for they are often found with tops quite blasted, and the passage of the lightning lower down marked by a gouge-like furrow. These furrows sometimes go completely round the tree like a screw, the reason of which, says Professor Colladon, is that the lightning follows the cells of which the bark is composed lengthwise, and in certain sorts of wood these cells are disposed spirally.

THE recent rain in the Punjab has been most seasonable: about half the *kharif* has been saved, and there is every

ground for anticipating a good *rahi*. Four months ago, in H-shiar-pore, *sur* was selling at 16 seers per rupee; it is now barely 8 seers; and wheat, which was selling at 32 seers, has gone down to 20 seers per rupee.

The drought in Upper India has been very severe and prolonged. In H-shiar-pore the rainfall from 1st April 1882 to 31st March 1883 was 14 inches under the average, the result being that a great many wells and tanks had run dry, and in many parts of the district the people were obliged, previous to the last rainfall, to send their cattle 30 and 40 miles off down to the Beas and Sutlej Valley for grazing and water, the low hills and submontane tracts being quite bare, tanks dry, and no green grass left.

In a little work, published at a shilling by Cassell & Co., "An Old Exhibitor" gives his experience in potato culture. With the view of stopping the ravages of the disease, he recommends early planting and early lifting; the proper selection of healthy worts; and the substitution of manures with suitable chemical ingredients for gross farmyard manure. The disease, he agrees, is due to atmospheric influences, and is supported by dampness and shade, the former of which can be counteracted by drainage and keeping the soil in a loose, dry state, and the latter by thinning out the stems and foliage as they become too thick, and so exposing the surface of the ground to light and air. A common source of disease is the fermentation that takes place in heaps of green tops, and which causes the malaria to spread in all directions; the shaws should therefore be carried away at once and buried. At planting time, too, the unused potato sets should not be left in a heap on the field, because they quickly ferment and throw off a gas which carries with it the germs of the disease. The author is strongly opposed to the notion that potatoes should have a long period for ripening in the ground after the crop is completed, believing that nothing tends so much to produce disease. As soon as the tubers are fully grown, he recommends that they should be lifted and stored, any delay having only the effect of increasing the risk of disease. For keeping potatoes any length of time he finds the handiest and safest plan is to store in heaps on the ground, every precaution being taken to guard against the four enemies of the tubers—frost, wet, disease, and light.

The writer also advises those entering on experiments to raise their own seed and grow their own sorts, in preference to grafting one stem on another or grafting eyes. He believes the latter method will fail to produce distinct varieties. A light fibrous loam is the most suitable soil for the potato, and thorough cultivation is necessary to its successful growth. He considers horse-dung the best manure for cold, wet soils, and cow-dung for hot, light soils, with a top-dressing of guano, potash manures, soot and salt or bone manures. He does not favour Mr. Jensen's theory of earthing-up. A sharp ridge, in his opinion, causes the crop to suffer from drought, the rain being carried away from the roots of the plants; a hollow along the top of the ridge would cause an excess of moisture; but an inch or two of earth placed around the stems would strike the happy medium, and yield dry, clean tubers in the greatest quantity, and of the best quality. In preparing sets, due regard should be paid to the position of the eye on the tuber, as the shape of the tuber depends very much upon that. He agrees with the opinion that there are a separate set of fine tissues or vein-like threads for each eye, and experiments have shown him that in cutting potatoes for sets, sufficient width and depth of flesh must be left around the eye that is intended to produce the crop. They also proved to his satisfaction that when the cut is made too near the eye, or when the portion left is very thin, the eye is weakened by the fibres being interfered with. "An Old Exhibitor" argues that the potato is about the most profitable thing that can be brought into the market, and that the French and Belgian competition can be met by earlier and thicker planting, if the drills were only a foot apart, the sets eight inches apart, and the seed so sorted that each set is only allowed to make one sprout. If planted in the second week of March, they should be full grown by the first week of June, when potatoes are selling at about 2s. per stone; and a medium crop from his method of planting would be 4,840 stones per acre

which would yield £484, a very handsome return for the outlay.

The writer concludes his little brochure by giving a descriptive list of known varieties of potatoes suitable for cropping, indicating those which are likely to prove most satisfactory.

It appears from statistics that there are in the world no less than 3,985 paper mills, producing yearly 959,000 tons of paper made from all kinds of substances, including rags, straw, and alfa. About one-half the quantity is printed upon; and of these 476,000 tons, about 360,000 tons are used by newspapers. The various Governments consume in official business, 100,000 tons; schools, 90,000 tons; commerce, 120,000 tons; industry, 90,000 tons; and private correspondence another 90,000 tons. The paper trade employs 192,000 hands, including women and children.

The following is a letter from Deputy Surgeon-General M. C. Furnell, M.D., Sanitary Commissioner for Madras, to the Chief Secretary to Government:—

I have the honor, with reference to the Order of Government of 11th July 1883, No. 841, Revenue, on an inquiry to be made regarding a disease said to be prevalent amongst sea-fish, to report that I find certain steps have already been taken by this department, before the above order was received, which it would be as well Government should be informed of.

During my absence on privilege leave a letter was addressed to Dr. Bidie, Acting Sanitary Commissioner, from the French Vice-Consul of Madras, enclosing another from the Government of Pondicherry, in which latter it was stated that the sanitary authorities of that town had, on examination, discovered worms in certain sea-fish, "*qui eu rendent l'indigestion dangereuse pour la santé*," and asking if the like phenomena had been observed in our territories.

In reply, Dr. Bidie remarked that no official information had reached this office regarding sale of diseased fish in Madras, but that the rumour prevalent in Pondicherry on this head had made its way to this town, and that many persons in consequence refrained from, as usual, using fish as food. In the meanwhile he would be glad to be furnished, from the French authorities, with more detailed information as to which species of fish had been found unwholesome, and what sickness had arisen therefrom. To this letter, dated 9th June 1883, no answer has as yet been received.

About the same time the President of the Municipal Commission, Madras, and the Commissioner of Police, Madras, were addressed for any information they might possess on the subject, and the Museum assistants were instructed to make careful dissections of fishes, and preserve any parasites that might be discovered therein.

The answer of the President of the Municipal Commission, copy of which is attached, was to the effect that a belief was prevalent in Madras that many species of sea-fish were diseased, and that the consumption had decreased and prices fallen, but that at the time of writing (June 20th) the scare was passing away and trade resuming its normal condition. He enclosed a list of fish in which parasites had been found, but ends his letter with the following remark:—"I have heard of no case of sickness or disease from eating fish."

The Commissioner of Police was not able himself to send any information of a useful nature, but enclosed the reports of four Inspectors of divisions. Two of these speak of there being a rumour, but that in their divisions it had not deterred the people from using fish as usual. In Triplicane the people have been alarmed, but the Inspector had not heard of any ill-effects having arisen. The scare at the time of his report (June 15) was subsiding. The fishermen blamed the mutton butchers for the whole story, as a diminished consumption of fish, of course, increased their trade. In Mylapore, according to the Inspector's report, the scare seemed to have existed with greater force than elsewhere, and the people there labored under the belief that people using diseased fish would suffer from leprosy. A fish formerly sold for four annas fetched no more than six to nine pies.

Dr. Bidie informs me that the assistants of the Museum examined 122 fish, embracing twelve species of the kinds most commonly sold in the bazaars. Of the total inspected, 40 only,

comprising nine species, were found to contain parasites in the œsophagus, stomach, or intestines, but in no case was the flesh found to have an unhealthy appearance.

Since the receipt of the order (11th July 1888, No. 841, Revenue,) I have personally inspected the various fish markets, and find from inquiry that the trade has resumed its normal state, the scare having subsided. I have also examined a great many fish, and found parasites in only a very few: a more detailed account of these examinations will follow. My object at present is to inform Government of what has been done, and that the panic—if such it can be called—has apparently entirely subsided.

In a letter to Sir Louis Mallet, Mr. W. T. Thiselton Dyer, Royal Gardens, Kew, says:—I am desired by Sir Joseph Hooker to draw your attention to the steps which have been taken by this establishment to obtain information as to the lacquer industry of Japan. As you are aware, its products are highly esteemed by all lovers of art, but up till the present time practically nothing has been known as to the methods by which such beautiful objects are obtained.

From the statement of Kämpfer (1712), it has been accepted by botanists that the varnish, which is the basis of all lacquer work, was obtained from incisions in the three-year old stems of a tree indigenous to Japan, known as *Rhus vernicifera*. Beyond the fact that the tree is cultivated as coppice-wood, the information of Kämpfer does not go, and up to the present time our knowledge of the subject has been a complete blank. Thus Balfour in his *Cyclopædia of India* (1873) states that "the manner of preparing it (the varnish) and the mode of applying it, is and is likely to remain a secret." It had been supposed that the Japanese lacquer tree was identical with a common Himalayan species of *Rhus*. Dr. Brandis points out, however, (*Forest Flora*, page 121) that the Himalayan tree is not "known to yield any varnish;" and Sir Joseph Hooker in elaborating the *Anacardiaceæ* for the *Flora of British India* (ii, page 11) has, in describing it under the name of *Rhus Wallikii*, decided that it is not identical with the Japanese species. The lacques varnish tree of that country is apparently unknown in India. It seems worth while, therefore, to draw the attention of the Government of India to the fact, as seed could doubtless be easily obtained from Japan, and there are many parts of India in which the tree could be cultivated.

In its lac industry India possesses an art which is closely allied to that of lacquering. It can scarcely be doubted that the latter is equally adapted to the methods and habits of the natives. Its results are, in an economic point of view, infinitely superior to those in which lac is used.

At the instance of Sir Joseph Hooker, the Foreign Office caused an elaborate inquiry to be made by its officers in Japan into the whole subject. The result will be found in a report by the Acting Consul at Hakodate, dated Tokio, January 13, 1882, which has been printed and laid before Parliament. I am now to suggest that copies of this report, together with this communication, should be printed and transmitted to the Government of India, in order that some attention should be attracted to the subject in that country.

The very complete collection illustrating the report has been transmitted to Kew and exhibited in the Museum of Economic Botany. It has been pronounced by experts in Japanese art to be of exceptional interest and quite unique of its kind. A portion of the expense incurred by the Foreign Office in getting it together has been defrayed from the grant made to this establishment by the India Office for the sustentation of the economic-botanical collections relating to India.

I am desired by Sir J. D. Hooker to inform you that he received from Mr. Quin, Acting Consul at Hakodate, a small quantity of seed of the Japanese lacquer tree, *Rhus vernicifera*. Portions have been transmitted to Saharunpore and Madras for experimental cultivation. Mr. Quin states that these particular seeds were obtained "from trees which undergo a very severe winter, being almost buried in snow for several months." The tree, however, will doubtless do equally well in a less rigorous climate. Mr. Quin further states that the wax used in the north of Japan is all made from the berries of *Rhus vernicifera*.

MR. J. MILLS, in a letter to the Madras Board of Revenue, has the following remarks regarding the dietetic uses of salt:—It would be a difficult matter to say exactly what diseases originate from a want of proper supply of chloride of sodium, as it has never been recorded, so far as I know, that any of the herbivora have absolutely been deprived of it, for the reason that it is always more or less present in their natural diet; at the same time, animals do suffer very much in a general way from the want of a sufficient supply of salt. This is to be accounted for by the fact that the blood, to be pure and wholesome, must contain a due proportion of chloride of sodium; there must, as it were, be a proper balance of its constituents, and if this is not maintained, we have a fluid circulating throughout the body which is unable to replace, to repair, to build up, or to compensate for the waste of tissue which is constantly going on in the animal economy, and the result is mal-nutrition and general ill-health. This has been frequently demonstrated, and an animal in this state is always more prone to attacks of disease of every description; but no hard-and-fast line can be laid down as to the exact nature of disease which might develop itself. Therefore, I confine myself to a brief description of the advantages of the use, and the bad effects of a want, of a proper supply of salt.

Uses of Salt as a Dietetic.—The constant presence in the secretions of salt, and necessity of it in due proportion in the blood, indicate the importance of a proper supply of it with the food. We perceive this in the instinct of animals; when it does not exist in sufficient quantity in their food, they will travel long distances and brave the greatest dangers to obtain it.

2. It is considered to be the natural stimulant of the digestive system, and to assist the blood in maintaining its fluidity, its stimulating properties, and its powers of self-preservation.

3. It gives flavor to and renders food more palatable; even fodder of inferior quality is readily eaten when properly salted. The preferable way of salting hay would be to sprinkle it over the different layers as the stack is being made up, which will correct the bad effects of damp and smut.

4. It is especially necessary to animals receiving cooked grains or roots, for the salt naturally present in such prepared food is usually in small amount.

5. By causing thirst, it induces cattle to drink large quantities of water, which in torpidity of the bowels and constipation (disorders which are extremely common among Indian cattle during the dry season of the year, when the herbage has little or no succulent properties) is most essential, as it softens and carries onwards through the stomach and intestines the hard and dry ingesta and feces, thus warding off *impaction*, which is a most troublesome and often fatal disease.

6. With cattle, sheep and goats, salt can be employed in the capacity of a purgative with great benefit, and is second only to Epsom salts (sulphate of magnesia), and can be used to empty the bowels in distention of the rumen with food or gas (tympanitis) in impaction or diarrhoea, depending on over-feeding or kept up by the presence of irritating matter in the digestive canal. In fact, it may be given with the utmost safety as a purgative in all diseases where it is found desirable or necessary to open the bowels.

7. Small and repeated doses have an alterative effect, and are useful in all animals in indigestion and irregularity of appetite.

8. From its action as a stimulant as well as the cold it produces during solution, it is of great benefit in various diseases of the joints and feet, particularly among cattle, sheep and goats.

9. Salt has the power of increasing the fertility of the male and the fecundity of the female, and it doubles the power of nourishing the fetus.

10. During the period the young are suckling, salt given to the mother renders the milk more abundant and more nutritious, and accelerates the growth of her offspring.

11. If regularly given, it lessens the liability to intestinal worms, and an injection of half-an-ounce of salt with a pint of water will often bring them away from the large bowel.

12. The body of an animal getting a regular supply of it becomes an unsuitable habitat for the parasite world in general; consequently, it is a highly valuable agent as a preventive against the attacks of these pests.

13. For preventing and arresting putrefaction, salt is cheap and effectual, and stands on the list of antiseptics next after carbolic acid. For antiseptic purposes it is advantageously conjoined with carbolic acid. To disinfect skins and other animal substances a pound of salt and two ounces of carbolic acid are used dissolved in a gallon of water.

Effects of want of Salt.—Experiments have shown that animals deprived of salt, other than that naturally contained in the food, soon get heavy and dull in their temperament, fall off in condition, and have a rough and staring coat. The process of digestion is materially interfered with, and they become in every way liable to contract disease. It has also been proved that animals which do not find sufficient salt in their food or drink become less prolific, and the breed deteriorates.

| | | Doses. | |
|--|-----------------|--|-----------------|
| Purgative (to empty the bowels) | Buffalo | ... | 1½ to 2 lb. |
| | Ox | ... | 1 to 1½ " |
| | Sheep and goats | ... | 1 to 2 ounces. |
| Alternative (to alter the constitution from a diseased to a healthy state) | Buffalo | ... | 2 to 3 ounces. |
| | Ox | ... | 1 to 2 " |
| | Sheep and goats | ... | 1 to 2 drachms. |
| Stomachic (to improve the appetite and promote digestion) | | The stomachic dose may be looked upon as a proper daily allowance for animals in health. | |

To half-grown animals, give half the dose.

Endorsement by W. Wilson, Esq., Director of Revenue, Settlement and Agriculture, dated 20th June 1883.—

OFFICIAL PAPER.

EXPERIMENT IN SERICULTURE.

From J. B. FULLER, Esq., Director of Agriculture, Central Provinces, to the SECRETARY to the Chief Commissioner, Central Provinces,—No. 304, dated Nagpore, the 23rd July 1883.

I HAVE the honor to submit the following report on the experiment in Sericulture which was conducted in Chindwara during February, March, and April of the current year.

2. The object of the experiment was to discover whether the climate of the Satpuras was suitable for growing Japanese silk on the system which is followed in the Dehra Dun. The peculiarity of this system is that only a single crop of cocoons is raised in the year, whereas in Bengal several crops are raised in succession. The eggs are hatched at Dehra in February, and the cocoons are ready by the end of March. The eggs which are retained as seed for the next year's crop are then sent up to Mussoorie, where the comparatively low temperature prevents them from hatching until brought down again to Dehra in the February of the following year. In Bengal, on the other hand, the eggs resulting from the spring crop of cocoons are allowed to hatch out during the rains, and the eggs resulting from the rain crop are allowed to yield a third crop in the autumn. The deterioration of Bengal silk has been ascribed to this (the polyvoltine) system of culture. The rain and autumn crops of worms have to endure a climate which is unsuitable for them, and the breed becomes in consequence permanently enfeebled. The choice between the Dehra and Bengal systems lies between having one crop of good silk in the year, and having several crops of silk of poor quality.

3. In Circular No. 24 F. and S., dated 5th June 1882, the Government of India, in the Department of Revenue and Agriculture, offered to supply the Administration of these Provinces with 2 ozs. of silk-worm eggs from Mussoorie if an experiment was undertaken with them. For successful silk-growing, it is necessary that the climate should not become very hot until the worms have finished spinning their cocoons, that is to say, until the end of March or beginning of April. In this respect the climate of the Satpura districts in these provinces most nearly resembles that of Dehra. The station of Chindwara stands at a height of over 2,000 feet above sea level, and has a climate typical of the Satpura region. There were a sufficient number of mulberry trees in and around the station to provide foliage for a small trial. It was accordingly determined to make the experiment there. So far as management was concerned, the experiment was made under exceptionally favourable circumstances. The Deputy Commissioner, Mr. Tawney, took a lively interest in it, and made excellent arrangements for its proper conduct. The immediate charge of the experiment was committed by him to Mr. DeLango, second clerk in the district office who carried out his instructions zealously and carefully, and has submitted a very good report. Since no one in Chindwara had any practical acquaintance with silk-rearing, it was considered advisable to import a trained man from Dehra, who does not however seem to have rendered much real assistance. His pay and travelling expenses (Rs. 158-14-2) constitute the heaviest item in the cost of the experiments.

4. Two ozs. of Japanese eggs were received from Mussoorie on February 10th, and between that date and February 25th,

3 oz. was hatched out by exposure to the sun. This is calculated to have yielded some 30,000 worms. Hatching was then discontinued, since it was believed that the supply of mulberry foliage would not be sufficient for a larger number of worms,—a belief which was found to be incorrect as events showed that the mulberry trees which Chindwara contained could have supplied food to eight times this quantity. The hatching out of the worms, has to be so timed as to take place when the mulberries are coming into new leaf, and might in the present case have been effected sooner with advantage. Mr. Tawney believes that February 5th is, in ordinary years, a safe date to calculate upon.

5. It was originally intended to erect a cheap rearing shed of brushwood, but it was found possible to utilize an old brick cattle-shed, which suited the purpose well. The treatment of the worms is described as follows in the district report:—

"As the worms were hatched each day they were put into bamboo trays, with the date affixed, and fed on tender leaves, cut very small.

"After a few days the stronger worms would come to the top, and these were again removed to other trays bearing the same date: and so on, till the contents of each tray were distributed into several other trays, to prevent overcrowding. The worms were not handled, but removed from tray to tray by means of small pinners, the leaves being lifted with the worms on them.

"For about 20 days they were kept in trays and then removed on to the tables, when they were fed on whole leaves. The tables were cleaned every second day."

For the first 20 days the worms were fed on detached leaves cut into small pieces. After this leaves were given them in branches, twigs and all. The leaf given to the worms each day was carefully weighed, and the total weight of foliage used in the experiment was found to be 59 maunds. The superficial area of the trays in which the worms were reared was 130 square feet. This is one-third more space than that allowed in Italy, but one-fifth less than the space which was found necessary in the Dehra experiments.

6. The mulberry trees in Chindwara were of two varieties, one having much thicker leaves than the other. Mr. Duthie, Superintendent of the Saharunpore Botanical Gardens, to whom specimens of both varieties were submitted, pronounced the thicker-leaved one of the two to be *Morus atropurpurea*, and the other to be *Morus indica*, the mulberry ordinarily used for silk-growing in Bengal. The Dehra silk-rearer from the first preferred the thicker-leaved variety, and the results have shown his preference to have been justified. The worms fed on each variety were kept carefully separate, and the thick-leaved mulberry has been proved to yield much the best silk (see para. 12).

7. The first cocoon was spun on March 22nd, thirty-two days after hatching. The following arrangements were made:—

"To enable the worms to make their cocoons, whole branches with leaves were spread over them, the leaves serving as food for those that had not commenced at yet; other contrivances were also made by tying 3 branches of cypress together and spreading them like a triangle over the worms; to these they took readily, and the cocoons made on these were cleaner and better than those made under the leaves and branches of other tables."

8. It is interesting to note here the temperature which the worms had to endure. It was recorded three times daily, at 7 A. M., 2 P. M., and 10 P. M. The highest temperature registered up to March 19th, was 90°, which occurred on five days before that date. The lowest temperature registered was 68°. On March 20th and 21st, the thermometer marked 92°, and on March 22nd rose to 94°, which was the maximum registered on each subsequent day of the experiment. After March 22nd the minimum was never below 72°, and on several days the thermometer never fell below 82°. Water was sprinkled on the floor of the shed to keep the temperature down, but it is probable that it was considerably hotter than a grass shed would have been.

9. The cocoons were weighed as they were cleared each day from the tables, and their total "green" weight was 41 lbs. 12½ ozs. A portion of them were "sun-dried," the chrysalides being killed by exposure to the sun. Another portion were "steamed" at my suggestion in the simple manner used by rearers of tussar silk in Chhattisgarh districts. The process is described in the report as follows:—

"The steaming was effected by means of 2 pots; the lower was half filled with water; and a wire flour sieve was put on its mouth into which the cocoons, a pound at a time, were put; the other pot, its mouth having been broken off, was inverted over the lower one, so as to prevent the steam escaping. Within 15 minutes of each steaming the chrysalides were killed thoroughly, as was tested by opening a few. The steamed cocoons were then dried in the shade, weighed and put away."

10. When thoroughly dry the cocoons were re-weighed and amounted to 14 lbs. 14 ozs. They had therefore lost two-thirds of their weight, those which were "steamed" losing rather less weight (62 per cent) than those "sun-dried" (66 per cent). They were then despatched to Messrs. Thomas and Co., Brokers of Calcutta, who had kindly engaged to have the silk spun and valued. The spinning was effected in the Berhampore factories of the Bengal Silk Company. The cocoons yielded 4 lbs. 5 ozs. of spun silk, and the following product: possessing mercantile value:—

| | | | | oz. |
|--------------|-----|-----|-----|-----|
| Tape Chassum | ... | ... | ... | 10 |
| Feshwa No. 1 | ... | ... | ... | 1 |
| Feshwa No. 2 | ... | ... | ... | 1 |
| Godhur | ... | ... | ... | 2½ |

11. The success of the experiment depends upon the quantity, as well as upon the quality of the silk produced. As regards the quantity of produce, it is possible to test the results by comparing the proportion of cocoons to eggs and of silk to cocoons with the ratios which are accepted as the standard in works on Sericulture. This comparison is effected below :—

| | Standard | In the experiment under report. |
|------------------------------|------------------------|---------------------------------|
| One oz. of eggs yield ... | from 20 to 23 lbs. dry | 19.8 lbs. |
| Four lbs. of dry cocoons ... | cocoons. | ... |
| yield ... | ...one lb. silk | 1.16 lbs. |

The ratio of cocoons to eggs is very nearly up to the standard, while the ratio of silk to cocoons is above it. This is one of the most satisfactory points in the results, since it proves that the cocoons were above the average size and weight.

12. The best indication of the quality of the produce will be afforded by quoting the Calcutta report. Of the cocoons Mr. Stocks, the Manager of the Berhampore silk factory, writes :—

"I went through the cocoons carefully and weighted them. The sun-dried and the steamed appeared much of the same quality. I preferred the latter, and they have given better produce. The double cocoons were not more than 3 per cent, and the useless ones 1 per cent. I should say that these two lots were worth Rs. 3-4-0 per seer dry. The sun-dried China Mulberry ones were a poor lot,—2 per cent of double and one-fourth stained. I should say Rs. 2-8-0 per seer dry a high value for them.

"The silk is very good from the thick-leaved Mulberry cocoons, but you will find it does not open so freely as good silk should; the great heat required to unwind the cocoon is to blame for this."

"I made the silk 12-13 deniers, and it was carefully reeled so."

It is noticeable that the worms fed on the thicker leaves of the two varieties of Mulberry (*Morus atropurpurea*) gave much better cocoons than those fed on other variety (*Morus indica*), termed the China Mulberry in the above report.

The Brokers' report on the spun silk is as follows :—

"We have examined the two large bundles of raw silk the produce of the sun-dried and steamed thick-leaved Mulberry cocoons.

"There is no noticeable difference between either of these bundles or the three skeins from the sun-dried China Mulberry. We report the quality to be decidedly good; the colour is a good white, but in some skeins there is a slightly greenish tinge and in others a leaden shade. It is also very clean; some slight show of small knit, but hardly worth notice except in a critical report: the size is 12 to 14 deniers, but is not so reliable in this respect as we should like to see it. However, without some experience of the yield and nature of the cocoons the reellers are handling, they are at a great disadvantage; in the present case we consider the reellers have been quite as successful as could be expected—the silk winds very well.

"The yellow skein we have not opened, as we think you would like to receive it in a fresh state; it doubtless will bear just as good a report as the others; the only special remark to make is, though the colour is bright, it is not of the brightest."

It will be noticed that no market value is quoted for the silk, because, in the words of the Broker's report—

"If valued as Bengal raw silk we could not put the value higher than Rs. 16 to Rs. 17 per factory seer, whereas it is the writer's opinion that if the silk be submitted for valuation in Europe and is not supposed to be Indian or Asiatic silk, it will be valued at about 30s. per pound in London, running certain kinds of European reeled silk, to wit, Brousses, very close.

"We could suggest that you send forward the samples to London, Marseilles or Lyons for careful report and valuation, but if this be done the writer ventures to counsel you, if you desire to get a perfectly unbiased report and value, to take some pains to disconnect the silk with India, with which object Indian tickets, paper and packing should be destroyed, and skeins should not remain banded and tied up as now in packets of three and four ere they pass into the hands of the expert at home. On no account send forward any of the cocoons—chassum or other waste: these would serve as a connecting link.

"In conclusion we have only to remark that the Bengal Silk Company work the filatures formerly owned by Messrs. James Lyall and Co. This company would like to secure a good supply of such cocoons as they have reeled for your department, and we and they will be glad to learn that your department sees its way to increase the production and to know at what rate this is expected to take place."

The silk was therefore of a quality greatly superior to that ordinarily produced in Bengal, and equal to certain classes of European silk.

13. Messrs. Thomas and Co. have favoured me with the following additional remarks on the waste products (Chassum, &c.) mentioned at the conclusion of para. 10 :—

"Besides the raw silk produced from the cocoons we return you the waste or refuse, which some 20 years ago had only a nominal value."

Tape Chassum appears very good of its kind, but we can't say that the valuation we now put on it of Rs. 175 per factory maund would be obtainable, because it is white; as a rule, there is a prejudice against white Bengal Chassum, because at the dyepot the white of Bengal silk and Chassum can't be relied on as true white, and not being a yellow, it becomes a bastard colour. But in the writer's opinion this white Chassum will prove perfectly reliable as

a white silk, and with consumers' minds set at rest on this point, the valuation of Rs. 170 ought to-day to be obtainable. Rs. 170 is an extremely high value. This class of Chassum has never sold so high in former years. Last year Rs. 160 was the rate, the previous year Rs. 140. Before these years the price ranged between Rs. 125 and Rs. 140 per factory maund.

Freshia No. 1 is worth nearly as much as the Tape Chassum, selling along with it in the contracts we pass.

Freshia No. 2, worth about Rs. 80 per factory maund.

Godhar or Low basin waste and husks, worth about Rs. 20.

14. The experiment may therefore be pronounced to have been a complete success. It was, it is true, on a very small scale, but the results are sufficient, I think, to establish beyond doubt that excellent silk can be grown in the Satpura tract, if eggs were imported from Mussorie, and only a single crop taken in the year. And in addition to this, the experiment was conducted with so much care, as to furnish a number of reliable data which will be extremely useful in the event of sericulture being taken up on a large scale. On this subject, which is directly connected with the extension of mulberry plantations, I will do myself the honor of addressing you in a separate communication.

15. The total cost of the experiment was only Rs. 292-14-6, considerably more than half of which (Rs. 158-14-2) was incurred on the salary and expenses of the silk-reaver imported from Dehra. Economy is therefore another point for which Mr. Tawney is to be congratulated on his management.

J. B. FULLER,
Offg. Director of Agriculture.

SELECTIONS.

THE ONTARIO AGRICULTURAL COLLEGE.

By PROF. W. A. HENRY.

IT was early on a bright morning of the present month that I started from the hotel in Guelph for a visit to the Agricultural College. Leaving the quiet little city with its walls of dull, grey limestone behind, I passed out on the Duudas-road, and after a brisk walk of a few minutes found myself at the college gate. The first rapid sweep of the eye over the scene brought nothing very interesting or striking to view; in the background on a rise of ground fronting me stood a long three-storey building of the same gray limestone as that used for buildings in the city. This main building was flanked on one side by a couple of neat dwellings, and on the other by a cluster of barns and out buildings, while in front of these last, half hidden in the trees, stood a green-house. The grounds in front of the main building were treeless, and having been recently ploughed up, lay bare and brown.

To one brought up in the United States where the idea largely prevails that immense buildings are prime factors in the make-up of a college, the sight was not very prepossessing, and yet this institution, situated away to one side of the centre of our American civilization and almost on the outskirts, has of late attracted much attention from those studying the problem of industrial education, and caused many persons like myself to make long pilgrimages, even in some cases from across the Atlantic to study the causes of its success. In the United States we have scores of colleges with buildings far more massive than these, and whose age renders them venerable compared with this new thing, yet their fame has scarcely extended across the borders of the county in which they exist.

But I have kept the reader entirely too long outside the grounds contemplating the earthy campus and the gray-stone buildings. I was not long in making my way to the office of the president, James Mills, who gave me such a welcome that I felt at ease at once. With him as guide, the professor of agriculture was soon found, and I now had my two main sources of information at hand. Let me give to the reader some of the facts gathered.

This college accommodates 130 agricultural students, who all reside in the main building under the direct supervision of the president. Each candidate for admission has to pass a thorough examination in the common English branches upon entering. The course of study is two years in length, and is made to combine both the practical and theoretical. All students naturally fall into one of the two classes—"First Year" or "Second Year" students. Each class works daily five hours in the fields, barns or workshops, and have five hours for study and recitation. The work and recitations of the two classes alternate; thus, while the first-year boys are with the professors in the class-room during the forenoon, the second-year students are employed, under the guidance of proper superintendents, at manual labor in the fields, barns or shops. During the afternoon the order is reversed. For this manual labor the student is allowed from four to ten cents per hour, according to his ability. His earnings are credited on his board account. For board, washing and lights the cost is about ten dollars per month. The cost of the year's schooling is, to a good, working student, not over sixty dollars per year for all expenses, except clothing.

All students are treated alike as to hours of labor, and the endeavour is to make each familiar with all the varied farm operations. To be sure, with only a two-years' course, and half of the day spent in the field, no extended course of instruction can be given; yet, since no time is spent on any foreign language, the student is given a fair start at least in such sciences as botany and chemistry. And is given a good drill in English. The range of study and thoroughness is more than one would suppose at first thought. The average student leaves the college an intelligent man, if not an educated

que. It is in the practical operations that this school excels. Let me illustrate by showing how the young men are taught in regard to stock. When Professor Brown takes up this topic, his lectures are illustrated by the living animals. When talking about Short-horns, for instance, a bull or a cow of this breed is led into the lecture room and studied. Before the subject is left, several individuals are brought in at once and compared. After this course with each breed, representatives of different breeds are placed before the class, as Herefords, Short-horns and Polled Angus, and comparisons made. Nor does this end the matter. Each student must pass an examination upon these lectures, and in a most rigid way. When being examined the student is alone in the room with the stock, the Professor and some practical stockmen chosen for the occasion. It is not to be wondered at that these young men become very proficient in such matters. It is in ways like this that the whole farm is made to serve as illustration.

The farm is very complete, and I wish this whole paper could be given up to an account of it. It consists of 550 acres of choice land. There are twenty-one fields of twenty acres each; there are seven fine teams of work-horses and all sorts of farm machinery, without limit, almost; there are on the farm seven breeds of cattle, six of sheep and three of swine.

The college is now about to take a step in advance. Several years ago, \$10,000 were spent in blooded stock. This has paid handsomely, as over \$15,000 have been realized for surplus stock sold out of this herd. This fall they propose to hold a clearance sale and re-stock the farm with a larger number of animals of a higher type. Not only is there to be a great change in the stock, but the college grounds are to be metamorphosed. Mr. Miller, who laid out Fairmount Park, Philadelphia, has been employed to remodel the grounds, and the work has already begun. This accounts for the large lawn in front of the main building being ploughed up, as mentioned at the beginning of this article. In place of their present small green-house they are to have one costing over ten thousand dollars, and all the barns are to be torn down and new ones built on a new site. These progressive changes are a measure of what the Ontario people think of their agricultural college.

President Mills informed me that if he wished he could fill this school with young men from England alone, and that the cities of Canada would over half supply the list. His endeavour, however, is to have the sons of farmers from Ontario fill the school. So long as this is not the case outsiders will be admitted. Last year sixteen young men from England were in attendance, Ireland and Scotland sent three each, and Turkey, Wales, the United States and West Indies each sent one. Each term he has to refuse many applications for admission. President Mills says that so far as he knows every student who came to the College from the farm has gone back to the farm when through. Let those who claim that education drives young men from the farm ponder over this statement.

The reasons for the success of this school can be found in the men and the methods. Those in authority have turned themselves squarely to the farmers of Ontario, and sought to know what under present conditions should be taught to their sons to make good farmers out of them. They have not looked to classical colleges for guidance, but have been governed by the needs of the common people. Who could expect anything but success when such methods have been employed? No wonder money is beginning to flow towards this school like water, and both political parties of Ontario are claiming the college as their own particular child. Without fear of successful contradiction, I call it the model agricultural college of America. Less than ten years of age it is fairly rooted in the hearts of the farmers of Ontario. How can it have other than a bright future?

It was the afternoon of the second day when I closed my visit. I felt as I left that I could profitably stay a week studying the reasons why this young school was so rapidly gaining distinction. —*Farmers' Review.*

AGRICULTURE IN MOZAMBIQUE.

THE only agricultural industries that can be said to have firmly and successfully established themselves in the province of Mozambique, appear to be those of the cultivation of the oil-producing plants, *Amendoim* and *Gergelim*. The production of these, says Consul O'Neill, together with the collection of India-rubber, calumba root, and orchilla weed, forms five-sixths of the total exports of the province. This cultivation, and the labour requisite for the collection of the latter products mentioned, is conducted solely by the natives. Efforts have been made, from time to time, by the Portuguese and other colonists, to introduce the cultivation of other produce for which both the climate and the soil are especially favourable, but none have been thoroughly successful. Of the greatest importance have been the endeavours in various parts of the coast to raise sugar, opium, tobacco, and coffee. As the cultivation of *amendoim* and *gergelim* is entirely in the hands of the natives, it follows, as a natural consequence, that every stage of the working is of a most rude and primitive kind. The thousands of acres that are utilized in the cultivation of the seeds are cleared in great part with an axe of native make, of tomahawk shape, and with an edge hardly two inches in length. In some parts, particularly in the European settlements, a species of bill-hook is also used for clearing the undergrowth, but these two form the only tools of the Makua forest-clearer. The vast area of country cleared is then turned over by both men and women with a rough and clumsy hoe, also of native make, the slow working of which entails an enormous and unnecessary consumption of labour. In the sowing of *amendoim*, holes are made in the ground some little distance apart, generally three or four feet, to allow space

for the creeper to radiate. This is usually done with a sharp-pointed stick. One seed—care is taken that it is only one, as the natives declare that the growth of two or three will strangle each other—is then dropped in each other hole, and the earth stamped over by the feet. In the sowing of *gergelim*, the seed is broadcast as with grain, and scattered thickly over the ground. The sowers are then followed by others with hoes, who work the seed roughly into the ground, stamping the whole in with their feet. Care and therefore much labour is required to keep the ground clear of weeds that spring up in this climate and soil with astonishing rapidity, and throughout the growth of both these plants, the plantations are carefully tended. In the reaping or collection of *amendoim*, the plants are simply pulled up by hand, and the tubers taken off as with the common potato. They are then laid out to dry in the sun, and when thoroughly dried, are shelled by hand for the extraction of the seed, an operation requiring considerable time and patience. With *gergelim* the plant is in some districts literally reaped, but simply and by hand, with an ordinary knife. In others the plants are simply pulled up out of the ground; in the latter case they are then cut about a foot down the stem. The plants are now tied into small bundles, which are struck in the ground in the sun till thoroughly dried, when the seed will drop readily off. Large mats are then spread on the ground, the bundles taken up and shaken vigorously over them till all the seed have thus been extracted. With both *amendoim* and *gergelim* the seeds are then packed in baskets of native manufacture, and carried on the heads of the blacks, in some cases a distance of fifty or sixty miles, to the house of the coast trader, there to be bartered for cloth, beads, power, &c., and to be stored till an opportunity occurs. The sugarcane is cultivated by the natives upon most parts of the coast where alluvial soil exists, but only in insignificant quantities, and to be used by them as a sweetmeat, or for the purpose of chewing. The only part of the province where its growth has been attempted upon any considerable scale is in the rich soil of the Zambézi delta, and by the Portuguese planters of that district; numerous plantations exist there, and the cane grows luxuriously upon them. The only use, however, to which the cane has, up to the present time, been put, is that of the distillation of spirits. Consul Baring says, that beyond the Zambézi, there are many places in the province eminently adapted for the growth of the sugarcane, and which possess easily accessible and secure ports for discharge and shipment. Amongst these may be mentioned Mwambi Bay (Pomba), Mwondazi (Mwemba), the western shores of Nakaha and Nihegehe, on the branches of Fernao Veloso Bay, and the country to the south and in the vicinity of Mokambo Bay. Tobacco, though cultivated as an article of commerce for export, has not met with much success, as the passion for the weed has become deeply rooted in the natives of the coast and interior, so that it is cultivated by them in many parts of the province for their own consumption, and forms a regular article of sale and barter amongst themselves. The tobacco leaf is dried very carefully by the natives, and is made up in a peculiar way, as follows:—It is first plaited, and when the plait has reached a length of three or four feet, it is wound up in the form of a spiral. Gradually drying in this shape, it preserves its form without any binding, and it is unwound and cut off in short pieces when required for use or sale. This mode of preparation is invariable among the Makua and Yao, between the Mocima and Zambézi. Consul O'Neill says, that "were the natives instructed in some simple method of drying and the leaf, the valuable product would be probably brought down by them in considerable quantities, affording, as it would do, a larger margin for profit than does the culture of oil seeds, and it might become a regular article of colonial manufacture and export." Among the many plants useful to commerce that grow wild on the coast land and interior of Mozambique, may be mentioned the castor-oil plant, the senna plant, a species of sarsaparilla, the capsicum, or common red pepper, used by the natives with their food, but as yet not gathered by them for sale, in spite of the efforts of some merchants to induce its collection; and the pine-apple, the fibre of which has been lately proved to be a valuable substitute for flax. —*Journal of the Society of Arts.*

FRENCH AGRICULTURE.

THE supply of Percherons is falling short, and the Government is anxiously studying how to remedy the evil. Two measures are under consideration to prohibit altogether the exportation of the horses, and to augment the number of State breeding studs. Le Perche, from which the name of the race of horse in question takes its name, was an ancient region of France, and with Beauce, may, for general purposes be included in Normandy. It is a country full of beautiful valleys, is fertile, well-watered, and containing fresh pasturages of excellent quality. The soil is argillaceous, but not impervious. At the same time the water does not pass off rapidly. Thus it is favourable for herbage, including among others, peas, vetches, and sainfoin, and in some instances lucerne. The country, too, is well wooded, thus affording shelter and shed for the animals. There is no proof that the Percheron horse is of Arab origin. From time immemorial, from paintings and tapestry work, he appears to have been a good, general animal, of which a select number were kept for draught. Till last century the breeding and rearing of these horses was a monopoly in the hands of the rich land-owners and the monasteries. The young Percheron in those days remained in the country till the age of four years, and was purchased on the farms in Perche and Beauce, as also in the fairs of Eure-et-Loir. Here the dealers from Paris came to make their choice for posting and carriage horses. The army buyers, too, competed for the wants of the

cavalry, and above all, of the artillery. The present practice is more varied. Some sell the foals at the moment of weaning. Others buy them at the age of six months, and sell them when thirty months old. While, again, in the Beauce, the animal, bought when two-and-half years old, is trained to light work, and sold when aged five years, at a good profit, their work and manure paying for their keep. Strabo relates that the Satrap of Armenia sent every year to the King of Persia 20,000 young horses for the fete of Mithra. The supply of Percherons is not equal to this, but the demand is endeavoured to be met by spurious animals sent from the neighbouring departments, especially from Bretagne, Anjou, Maine, &c. The foals are left to suckle their mothers for five, six, or seven months; those that are not weaned till eleven months are not considered so good as the others. The foal begins to follow its mother from the ninth day, and when aged about two months, commences to take solid food. Weaned ordinarily at six months, the foals are allowed to live together till the age of three years. Shoeing is undertaken at this age. The fore-feet are shod first, and six months later, the hind feet. In Le Perche the farmers select the mares best suited for their purpose, and what most contributes to give fixity and homogeneity to the race is, the exigencies of Paris, which requires animals strong and full-bodied. Hence there is a uniformity of aim in selecting mares. The same observation applies to stallions, which chiefly come from the Beauce, though they may have left Le Perche when very young. Although in the latter country there are mares of all sizes and corpulence, there is a family likeness among them all, due to climate and local causes. Farmers have land of various qualities, and place thereon foals of different varieties; food becomes thus adapted to special types. The great point with the breeder is, to have a good mare. With a good mare you will have good fillies. If you want bus and cavalry horses, reject all Arab and English blood. If you want horses for the saddle, keep such blood. There are two classes of Percherons, the large and the small, the former being frequently confounded with the Boulonnais foals. Whether light or heavy the Percheron is required for the rapid transport of vehicles and goods, and ought to unite all the elements of zootechnic beauty in bone and muscle. The eyes ought to be large, the head small, and tapering towards the nose and mouth; skin fine, no coarse hair, head elegantly placed, and the shoulders well detached from the withers. The body of the mare, always longer than that of the horse, must not be too long; back straight and horizontal with croup; trunk of tall thin and springing well from the height of the croup; a broad croup indicates good action in hind legs, as a wide chest presumes the same in the fore-legs. The legs ought to be straight, large, and possessing little hair—tufts of hair and thick skin indicate liability to illness. A skin, fine to touch and slight, ought to characterize the whole body. Grey-colored animals are not to be rejected. Avoid animals with hard tumors on the legs, &c.; the feet should not be too small, nor too large. The stable ought to be well-aired by ventilating chimneys, and light freely admitted. In the fields the colts ought to be sheltered. In Hungary such is effectually secured by three walls. Feed well without producing fatness. A mare ought always to be in good condition. Carrots and parsnips are excellent. Indeed foals have been reared on carrots alone. Water breeding mares twice a day. If from a well, allow the water to acquire the temperature of the surrounding air, or employ a handful of bran. A little salt is good. When 2½ years old, when the first milk teeth commence to fall, colts can be set to light work, avoiding as much as possible that of a pulling or violent nature. In fact the first efforts ought to be exercise, not labor. In conclusion, to have pure Percherons, purchase them on the spot from the breeders. M. Schultz of Lupitz, Germany, is creating something like a sensation by his system of culture of sandy soils, rotating potatoes, rye, clover, pasturage, and lupine. His theory is, that lupine especially, and clovers, fix atmospheric nitrogen in the soil the more so when aided by the salts of potash, if applied in the form of kainite, which is but sulphate of potash. As for atmospheric nitrogen, &c., that is a point on which scientists are not at all agreed. But deep-rooting plants like clover and lupine (from lupus, a wolf, its roots being so penetrating and voracious), may induce combination in the organic matters of the soil, so as to induce nitrification more largely. M. Schultz employs a good deal of marl, an essential for lupine. He applies 4½ cwt. of kainite per acre, and obtains in lupine a yield of 19 cwt. of seed and 1½ cwt. of straw. While not accepting as demonstrated, that potash favors the absorption of atmospheric ammonia, it renders the phosphoric acid in the soil soluble, augments the consistency of sandy lands, keeps the earth fresh, and so aids vegetation. Harvest operations in the south of France are disappointing, but in the central and northern regions the yield is expected to be more satisfactory. The vines sadly want heat. The flowering, the critical stage, passed off most satisfactorily. As for the phylloxera, its march is ever forward. The malady is eating its way surely over France. Prospects of sugar beet are excellent. M. Bouley still maintains that it is better to feed pigs on the cooked carcasses of diseased animals than to bury the latter.—*Madras Mail*.

FRENCH AGRICULTURAL NOTES.

DURING the season of sugar-making the manufacturers employ the services of young chemists, at 200 fr. per month, to analyse the beet offered for sale, and on which the price depends. The season terminated, the chemists are dismissed, hence, the difficulty of obtaining their services later. It is proposed that for the future the sugar manufacturer employ the chemist all the year round; that in the slack period he could superintend experi-

ments affecting the growth of several varieties of beet, the distances at which it is best to plant them, the efficacy of several manures, &c. It is also proposed that the fabricants supply farmers, and at wholesale prices, not only with seed, but with appropriate manures. The prospect of the beet crop is excellent; the weather is propitious for the young plants.

Head Veterinary Inspector Bouley confirms his assertions, that the flesh of animals killed in the knackers' yards, even those diseased, can be given without danger, if well cooked, to pigs during their growth. It must be discontinued, however, during the fattening stage.

Mares, or the residue of the wine-press, have proved to be as good as pressed beet-pulp for feeding. Hitherto they have not been utilized. Sheep thrive well on the diet. It is best to employ mares for the first feed of the day, and to mix with the other rations. A little oil-cake makes an excellent mixture.

There exists an erroneous impression that for ensilage or trench food a special variety of maize is necessary. This is not so. All varieties have alike been tested in France without any difference being perceptible. The main object is to obtain the seed free from damage, so that its germinative power shall remain sound. The next end is to sow in lines from 10 to 20 inches apart. This allows of weeding; larger spaces induce the growth of thick stems, which necessitate the use of the chaff-cutting before the stuff be trampled into the trench. Maize for ensilage can be sown from May 1 to July 12; but in France, that sown between May 15 and close of June succeed best; 1½ cwt. of seed to the acre. The special manures consist of nitrate of soda, superphosphate of lime, chloride of potash, dried blood, or wool-dust; bone-dust can supersede the superphosphate in many soils, and when farm-yard manure is employed the fertilizers can be reduced by two-thirds.

M. de Rolliore's plan of preserving eggs fresh is worth knowing, since it is practised by merchants who deal in with twelve millions of eggs annually. The eggs, when laid or quite fresh, are gently struck against each other, to see if they be "sound;" next they are placed in a kind of earthen pitcher, having a very narrow bottom; when the vessel is full, a solution of quarter of an ounce of quick-lime to one quart of water is poured in. The lime water permeates the shell till it reaches the first membrane, rendering the latter impervious. The pitchers are then placed in a cellar, from where all light is excluded, but a uniform temperature of 44 to 46 degrees Fh., uniformly maintained. In the course of a few days a pellicle forms on the surface of the water in each pitcher—carbonate of lime—and that must never be broken till the moment for withdrawing the eggs. This process enables the eggs to be kept fresh for 6 to 8 months, and not more than five in a thousand prove objectionable.

A gardener keeps his frames and hothouses free from slugs, by mixing sulphate of copper with wheaten bran. The odour of the latter attracts the enemy to certain death. Keep poultry, however, from the stuff.

The vineyards are in excellent condition. Unhappily, the phylloxera continues its onward march. Of all the remedies propounded, autumnal inundations, followed by good spring manurings, is the most popular. All attempts to acclimatise the tubercular annual, Soudan grape, in France, have now been abandoned.—*Farmers' Review*.

BREEDING SEED GRAIN.

THE term "breeding," as applied to grain, will be regarded as misapplied. But it more clearly represents the idea in the mind of the writer than any other that could be chosen. Stock-breeding has for years engaged the attention of scientific and practical men in this and Europe, and the results are seen in the improved breeds of horses, cattle, sheep, swine and poultry throughout the country, while their influence in grading up the common stock is seen on almost every farm and ranch. The gardeners, nurserymen, seedsmen and florists have brought about great improvement in vegetables, fruits and flowers, improving old varieties, and devising new and valuable ones. But no such careful, painstaking, scientific effort has been directed to the improvement of the seeds of grain which form the staple of the farmers' crops. If improved varieties have been introduced they have largely been the result of accidental hybridizing or have been brought from distant localities, and under new conditions have for a time proved superior to varieties previously grown. There has been no careful breeding for improved varieties or improvement in quality, as has been the case with the live-stock men, the gardeners, nurserymen, and florist. It is, perhaps, incorrect to say there has been no effort in this direction. What is meant is that it has not by any means been general, or to any such extent as to make itself felt in the agriculture of the country. It has in no case passed beyond the stage of experiment in the hands of few individuals; yet such experiment indicates, if indeed they do not demonstrate, that by a careful system of "seed-breeding" as great an improvement can be made upon the grain crops of the country as we already see has been wrought in the live-stock interests, the improved quality of which is not only a source of greater profit to the individual farmer, but adds immensely to the value of our resources as a nation. The average yield per acre of wheat and corn in this country for the past ten years has been (omitting fractions), twelve bushels for wheat and twenty-seven for corn. If by improving the quality of the seed of these two crops the yield, without improved culture, could be increased 50 per cent, it would add to the annual income of the farmers of this country on the basis of last year's yield, at \$1 per bushel for wheat and \$0.50 for corn, no less a sum than 670,000,000 of dollars, equal to over \$13 per capita of our entire population, and yet it is morally

we certain that by pursuing as careful a system of seed breeding as has been pursued in stock breeding, such an improvement could be wrought out, as it is that a thorough-bred or grade short-horn or Hereford steer is worth more and pays a larger profit than the native scrub. The same principle of breeding is applicable in both cases. Selection of the best and breeding or propagating from that, taking care that the stock is not allowed to deteriorate. In live stock the selection is not difficult. In grain, how to select the best is a more difficult problem. But it is being thought out by clever and enthusiastic experimenters. The pioneer in this movement, so far as is known to the writer, is Major Hallett, F. L. S., of Brighton, England, who commenced his experiments in 1861, and has since continued them, an interesting account of which appeared in the July number of the *Popular Science Monthly*. He finds that in the cereals no two grains or kernels are exactly alike in productive power. That in every head of wheat or other grain there is one kernel, which greatly exceeds all the others in vital power, and which will transmit to a greater or less extent its character to all the grains produced from it. Of eighty-seven grains of wheat from two heads planted by him under precisely the same conditions, and in the same plot, one produced ten heads containing 688 kernels. No other grain produced anything near this, and the finest ten heads selected from the plot only gave 598 kernels, or ninety kernels less than the product of this one kernel. The next year he planted the grain from the largest head of the plant which produced ten ears, planting in a row singly, twelve inches apart. One of the kernels produced a plant which produced fifty-two ears. While the plants on either side of it in the row produced seventeen and twenty-nine ears respectively, and the finest of all the other plants produced forty ears. The same system of selection was pursued each year, the results being that the length of the ear was doubled, its contents trebled, and the tillering or stooling-out capacity increased five times. The general principles wrought out, or the law of vegetation discovered by these experiments, is summarized as follows:

1. Every fully-developed plant, whether of wheat, oats or barley, presents an ear superior in productive power to any of the rest on that plant.
2. Every such plant contains one grain which, upon trial, proves more productive than any other.
3. The best grain in a given plant is found in the best ear.
4. The superior vigor of this grain is transmissible in different degrees to its progeny.
5. By repeated careful selections the superiority is accumulated.
6. The improvement, which is at first rapid, gradually, after a long series of years, is diminished in amount, and is eventually so far arrested that practically a limit to improvement in the desired quality is reached.
7. By still continuing to select, the improvement is maintained, and practically a fixed type is the result.

The practical value which these experiments and results have for the farmer is in this, that when a superior variety has by a long course of experiment been developed, and its character fixed, its multiplication for purposes of seedling is so rapid that in a few years it can become widely disseminated among the farmers. The variety of wheat known as the "wild goose" wheat, it is claimed, was all propagated from a single grain taken from the craw of a wild goose. The origin of an Egyptian wheat is claimed to be a few kernels found in the wrappings of an Egyptian mummy. The development of improved varieties of corn is now claiming the attention of those in charge of our agricultural experiment stations and private investigators. Some important facts have already been developed, and important results may be looked for in the improvement of this crop. The farmer can easily pursue a course of experiment for the improvement of his seed corn. This requires a special patch, not necessarily large, to be devoted to this purpose. It should be at such distance from any other corn that by no possibility could the ears be fertilized by the pollen from any other field. As soon as in tassel, every barren stalk should be cut out that the fertilization will only be by fruitful plants. Selecting the best ears for seed, the same course could be pursued the next year, resulting unquestionably in a seed that would be vastly more prolific than the original seed. An interesting experiment would be to select for planting the experimental patch ears from stalks bearing two perfect ears, and remove not only the barren stalks, but the tassels of all on which two ears had not set, ensuring that the entire fertilization should be from stalks bearing two ears. The probable result of a few years of this practice would be to so fix the character of the seed that each stalk would produce two or more perfect ears.—*Farmers' Review*.

THISTLE-DOWN FOR TEXTILE PURPOSES.

AN article on the subject of recent experiments with thistle-down appeared in the *Newcastle Daily Chronicle* of the 28th June, and was followed by a letter which will be of interest to our readers. The article was as follows:—

Considerable interest has been awakened in the textile trade by the recent announcement that a new fibre had been discovered in the shape of thistle-down. Under any circumstances, it is only natural that an announcement such as this should have caused a momentary flutter in manufacturing circles; but when our neighbour, Mr. Fenwick, of Stockton-on-Tees, is bold enough to prophesy that thistle-down will completely "revolutionise the textile trade," the matter immediately becomes one of more than passing interest. Thistle-down, we are told, is "as soft as silk, and almost equal to it in strength; piece-goods can be produced from it

at half the cost of wool; for felting purposes it is destined to take a high position; whilst it will enter freely into competition with cotton, and also make the finest paper." If all this be true (and it is only fair to assume that Mr. Fenwick has reasonable grounds for making such emphatic statements), it certainly seems probable that thistle-down will ere long occupy an important place in our manufactures. But be this as it may, the fact remains, that certain manufacturers have been so much impressed with the "probabilities" of the discovery, that they are giving the matter their earnest attention at the present moment. The first point which, of course, suggests itself, is with regard to the practicability of using the down for textile purposes. Unfortunately we cannot have the advantage of Mr. Fenwick's personal experience. He is not a textile manufacturer, although he says that, for some years past, he has been "giving attention to the raw materials used by our Yorkshire and Lancashire manufacturers." It is not necessary, however, to go far afield to find some proof that thistle-down may be successfully manipulated in a variety of ways. Among the curiosities of the Dublin Triennial Exhibition of 1849 were to be seen two pocket handkerchiefs which had been made from thistle-down and presented to the Queen. The material, it is said, resembled the finest silk. We have also before us a letter from a large textile manufacturer in Huddersfield stating the results of a series of experiments which he made some years ago with the down gathered from the tops of rushes. It is obvious that although the down of rushes may be a good fibre for experimental purposes, it cannot be compared in texture with the down of thistles. Suffice it to say, however, that rush-down was found "easy of manipulation, and strong and slightly in staple." But a serious obstacle presented itself—the "down" could not be grown in sufficient quantities to remunerate the producer. Mr. Fenwick believes that no such obstacle as this will stand in the way of the adoption of thistle-down. Assuming that the experiments which are now being made by manufacturers turn out to their satisfaction Mr. Fenwick suggests that the vast tracts of waste moorland in England, Scotland, and Wales, should be utilised for the production of thistles. He believes it would pay the cultivator very handsomely if he sold his "crops" at a penny per pound. But what weight of thistle-down could be grown per acre? Mr. Fenwick puts the quantity down at three cwt., and he calculates the cost of cultivation so as to afford a handsome profit thus. Supposing that a tract of moorland of 5,000 acres is taken at 5s. per acre; this will represent a rental of £1,250 per annum. Then he puts down 2s. 6d. per acre as the cost of planting, gathering &c., which means another £625. To this he adds £150 as the salary of a general superintendent of operations, thus bringing the total expenditure up to £2,025 for the year. If then a crop of three cwt. were obtained every year from each acre of land and sold at a penny per pound, the income of the cultivator would be, in round figures, £7,500, or an annual profit of £5,475! These are Mr. Fenwick's figures, and we give them for what they may be worth, without pretending to express an opinion as to the basis of calculation. It will readily be seen, however, how Mr. Fenwick has come to the conclusion that the hard-pressed agriculturist may find a fertile source of profit by growing thistles instead of wheat! The question is one of widespread interest and importance. Mr. Fenwick has already brought it prominently under the notice of the India Office, and pointed out that the boundless tracts of waste land in our Indian empire would afford a splendid field for the growth of thistles. The discovery of new fibres is engaging the close attention of the Revenue and Agricultural Department of the Government of India just now. It is intended to make the extraction of fibres of all kinds a special feature of the International Exhibition to be opened at Calcutta next December; and, in view of this fact, it is not unlikely that thistle-down may be practically tested. In the meantime, people at home will await with interest the results of the various experiments which are now being made; and, should it be found that thistle-down possesses all the advantages which Mr. Fenwick claims for it, there is no doubt the supply would very soon become equal to the demand.

The letter in reply is dated July 4th, 1883:—

Sir,—Referring to your leading article of the 28th June on the above, it may be well to utter a note of warning, not against the adaptability of thistle-down for textile and paper-making purposes, but as to the danger of cultivating thistles on waste lands.

Thistle-down, being the seed of the plant, on ripening is liberated by the slightest breeze, and thus will travel for miles. If I am correctly informed, a home-sick Scotchman, who had settled in Australia, missing the sight of his national emblem, sent home for some seed, the result being, that once sown, the thistles propagated so rapidly as to become an utter nuisance, as they spread over a wide tract of country, it being almost impossible to eradicate them.

Fibres adaptable for paper-making, and some for textile purposes, can be obtained from nearly every plant of the vegetable kingdom, the questions to consider being suitability for the purpose and cost of production; to say nothing of the former, I am afraid the figures set down at 2s. 6d. per acre as the cost for planting and gathering would fall very far short of the mark, as well as the yield of three cwt. per acre.

Three patents were taken out in 1831 for the manufacture of paper from thistles, one by Lord Barriedale, a Scotch nobleman; but these were anticipated in 1800, by one Matthias Koops, a Dutchman, who published a book containing specimens of the thistle paper, also paper from wood, straw, hay, bean-stalks, and sundry other plants.

I am of opinion that anyone interfering with thistle will verify the truth of the motto "Nemo me impune lacessit"—No one touches me with impunity.—I am, &c.

THOS. RUTLEDGE,

There have been several patents for making paper from thistles, viz., that of—

GRAHAM'S PATENT WOOD PULP PROCESS.

MR. GRAHAM'S patent, of which a specification is now issued, does not differ so materially from that of Tilghman as to present very remarkable features.

The patent is for improvements in the method of treating certain vegetable fibrous substances for the production of fibres for spinning, paper-making, and other purposes, and relates to the method of treating such vegetable fibrous substances as are capable of producing fibres suitable for spinning, paper-making, and other purposes when treated by any of the known processes in which the fibrous substances are boiled or steeped in a solution of sulphurous acid, or a sulphite or bisulphite of soda, potash, magnesia, lime, or other suitable base and water, preferably in a closed vessel or boiler suitably protected from the action of the chemicals used (such a process being described in the specifications of English patents No. 2994, dated 8th November, 1866, and No. 385, dated 11th February, 1867, taken out by William Edward Newton as a communication from Benjamin Chew Tilghman), the boiler being fitted with a valve which can be opened so as to allow the gases and volatile hydrocarbons contained naturally within and around the fibres (either in chemical combination or mechanical adhesion therewith) to escape.

The main feature of Mr. Graham's claim is that in carrying out the process above described there is a constant loss of sulphurous acid gas going on, and consequently a continual weakening of the solution employed, in order to avoid which he employs the mono-sulphite (commonly called the normal sulphite) of potash, soda, magnesia, lime, or other suitable base and water.

Either of these substances or a suitable combination of any of them, and water, are placed in the boiler with the fibrous substances to be treated, and the temperature raised to, or above boiling point, and after the hydrocarbons, air, and gases natural to the fibrous substances have been driven out by the heat and allowed to escape through the valve provided in the boiler for this purpose, he pumps or injects into the vessel or boiler sulphurous acid either in its gaseous or liquid state, or in combination with potash, soda, magnesia, lime, or other suitable base (or a suitable combination of any of them) and water, in the form of a solution containing an excess of acid; or a solution of sulphurous acid may be injected in sufficient quantity to produce a solution containing an excess of sulphurous acid above that required to form, in combination with the base, a mono-sulphite or normal sulphite. The valve is then closed and the contents of the boiler again raised to or above the boiling point of the solution, the valve in the boiler being kept closed during the whole time that it is necessary to continue the operation.

The operation of injecting sulphurous acid or its combinations with potash, soda, magnesia, lime, or other suitable base and water, as above described, may be repeated from time to time during the boiling so as to fully maintain, and if necessary increase the strength and efficiency of the chemical solution employed.

According to this mode of treatment a saving of the chemical employed is effected, little or no sulphurous acid gas being lost during the time the gaseous hydrocarbons and other gaseous or volatile matters are being driven out of the fibrous materials. And further, by first treating the fibrous substances with a mono-sulphite, the fibres will become impregnated with the same, and thereby protected from any detrimental action that might otherwise occur during their first boiling for the purpose of driving out the air, volatile hydrocarbons, and other gaseous or volatile matter by heat.

Instead of boiling the fibrous substances in the mono-sulphite they may be soaked in a cold solution of the same, and then steamed, and the air, free hydrocarbons, and other gaseous or volatile matters, allowed to escape through the valve with which the boiler is provided, previous to their treatment with the acid solution.

In the case where he employs an open vessel or boiler the operation will be naturally carried on at the temperature of the boiling point of the solution employed, but the process, and also the mode of keeping the acid solution at a fairly uniform strength, or, if necessary, increasing the strength thereof, will be substantially the same as that above described when using a closed vessel or boiler, in which latter case the operation may be carried on either at or above the boiling point of the solution. When using an open boiler it is evident that the excess of sulphurous acid supplied during the boiling will be constantly given off in a gaseous state from the surface of the liquid, and must consequently be replaced by further injections, while the acid given off can be led away and condensed, so as to enable it to be again used if desired.

In cases where the vegetable substances are boiled with water in conjunction with potash, soda, magnesia, lime, or other suitable base in the form of an oxide, the injection of sulphurous acid or its combinations with potash, soda, magnesia, lime, or other suitable base and water, during the boiling, but after the air and volatile hydrocarbons have been allowed to escape, will also be beneficial.

Mr. Graham prefers to inject the sulphurous acid, or the combinations of the same, as above described, into the vessel or boiler at the bottom, and to cause it to come in contact with the solution therein before reaching the fibrous material, for which purpose he forms a kind of chamber beneath the boiler, and separated therefrom by a perforated disc or diaphragm of lead or other suitable material capable of resisting the action of the solution, so as to allow the latter to fill the chamber. To this chamber a pipe is connected through which the sulphurous acid or a combination of the same with a suitable base, as described, is forced, or injected by any suitable apparatus.

It will be necessary to coat the interior of the vessel or boiler, and the parts with which the sulphurous acid (or its combinations described) come in contact, with lead or other suitable metal or material capable of resisting the action of the same.

1st—Mr. Graham's claim, therefore, is the treatment of vegetable substances capable of producing fibres suitable for spinning, paper-making, and other purposes, either in a closed or open vessel or boiler, first with the normal or mono-sulphite of potash, soda, magnesia, lime, or other suitable base (or a suitable combination of any of them) and water, and when the gases contained in the vegetable substances have been driven off by heat and allowed to escape from the vessel or boiler, injecting into the said vessel or boiler sulphurous acid in the gaseous or liquid state, either alone, or in combination with potash, soda, magnesia, lime, or other suitable base (or a suitable combination of any of them) and water, or a solution of sulphurous acid, so as to form in the boiler a solution containing an excess of sulphurous acid above that required to form in combination with the base a mono-sulphite, and then subsequently boiling or heating the same, all substantially as herein described.

2nd—The injection of sulphurous acid, either alone or in combination with potash, soda, magnesia, lime, or other suitable base (or a suitable combination of any of them) and water, in the form of a solution containing an excess of acid, into a closed or open vessel or boiler, during the operation of boiling vegetable substances in order to produce fibres suitable for spinning, paper-making and other purposes, by treating them with water in conjunction with potash, soda, magnesia, lime, or other suitable base, in the form of an oxide or a mono-sulphite (called also a normal sulphite) thereof, such injection being effected after the gases contained in the vegetable substances have been driven off by heat, and allowed to escape from the vessel or boiler, and subsequently boiling or heating the same, all substantial herein described.—*Paper-Makers' Journal*.

THE BREAD-FRUIT TREE (*ARTOCARPUS INCISA*, LINN.).

WHILE there seems a sort of mania abroad at present for raking up, and discussing all sorts of plants producing valuable or imaginary products, reminding us of the old herbalists, there are several useful plants which seem to be neglected, and, as far as Ceylon is concerned, we may instance the bread-fruit tree, introduced to the island early in this century, and of which we have only one variety, and that a very inferior one, bearing only once or twice a year. No attempt has yet been made by Government or private individuals to introduce better varieties, several of which are known to exist in the South Sea Islands, unless it be the Hon. F. M. Mackwood, whose attempt to introduce good varieties failed in consequence of the plants having died on their way to Ceylon, from want of a proper mode of sending them, no doubt. The failure of the unfortunate Captain Bligh's first attempt to introduce the bread-fruit tree from the South Seas to the West Indies, in the "Bounty," is well-known, but in January 1793 he arrived in the West Indies in His Majesty's ship *Providence* having on board bread-fruit trees, and a vast number of other choice and curious plants. The bread-fruit of Dampier, Anson, Cook, Allie and others, which is a native of the Moluccas and the South Sea Islands, is likely to have been introduced to Ceylon by the Portuguese or Dutch before 1793, and is known to the natives as the *rata* (foreign) *del*. A close ally of the real bread-fruit, the *del*. *Artocarpus nobilis*, Thw., and one with a small fruit the *Artocarpus Lukouchea*, Rox., are natives of Ceylon, whilst the *Artocarpus integrifolia*, Linn., is a doubtful native.

When the Rev. W. Ellis, the accomplished author of *Polynesian Researches*, visited Ceylon in 1854 or 1855 he mentioned the fact that we had only one variety of the foreign bread-fruit tree in the island, and that a very inferior one: this fact was mentioned by Mr. W. Ferguson in his foot-note to Cameron's *Gardening in Ceylon*, in Ferguson's *Ceylon Directory* for 1863, p. 218, and has several times been alluded to in these pages since, and though they seem to have in the South Seas many varieties of the bread-fruit with large and small fruits, and of several qualities, some of them in fruit at all seasons, just as we have varieties of the mangoes in Ceylon, nevertheless, here we are in 1883 without any regular attempt except the one referred to, to introduce better varieties of the bread-fruit into Ceylon. The late Mr. Dyke, Government Agent of the Northern Province, for many years kept getting supplies of plants from the Western Province to be distributed in Jaffna of this valuable vegetable. Our Ceylon variety bears no seeds, but in the South Seas and West Indies, they seem to have seed-bearing ones called *Nucifera* or bread-nut tree, and seedless ones, *Apyrena* or bread-fruit tree.

In addition to the extracts we give from Bonnett's *Gatherings of a Naturalist*, who gives a list of no less than 24 varieties of the

MOTHER SWAN'S WORM SYRUP.

Infalible, tasteless, harmless, cathartic; for feverishness, restlessness, worms, constipation, &c. 10, at druggists. E. S. Madon & Co., Bombay, Gen. Agents.

bread-fruit, and Horne's *Pipi*, we would refer our readers for further information to Ellis's *Polynesian Researches*, vol. 1, pp. 39-43, Williams's *Enterprise in the South Sea Islands*, pp. 421-23, for most interesting facts on the different kinds and uses of the bread-fruit tree. We extract as follows:—

Next to the above-mentioned food-plants, comes the bread-fruit (*Artocarpus incisa*), which is a most useful as well as a highly ornamental tree. It sometimes attains a height of 60 feet, but the average is from 30 to 40 feet. In general its trunk will measure about 15 feet to the first branches, with a girth of 3 to 4 feet. It is a horizontal branching tree, with a cone-shaped head. The leaves of the young trees are sometimes 2 feet in length, and from 12 to 15 inches in width. Those of the older trees are little more than half that size. They are covered with rough hairs, which makes them disagreeable to the touch. Some of the varieties have leaves deeply lobed, and those of some others are almost entire. The fruit of some of these varieties weigh as much as 9 lbs.; that of others does not exceed 1 or 2 lbs., and 4 or 5 pounds may be reckoned the average weight throughout the group. They are in general cone-shaped, flattened at the base, or spheroid. The quality of some of them is excellent, dry and mealy like a potato; that of others is watery and insipid. They are either baked or boiled, and eaten alone, or with pork or fish. Sometimes they are made into puddings, or buried underground, and made into a *Mandrai* i.e., native bread. At all periods of the year there are some of the varieties in fruit, but the fruit is most abundant from the middle of February to the middle of April. In some of the native towns the trees are abundant, and groups of 20 or more, may frequently be seen scattered over land which had been cultivated. Large numbers of trees were destroyed in the wars that constantly occurred between different tribes,—the first acts of an invading force being to destroy food-plants and fruit-bearing trees of the tribe invaded.

One or more of the varieties of the bread-fruit bear seeds, but the most of them are barren. It is doubtful whether these seed-bearing trees are varieties of the *Artocarpus incisa*, or if they do not form another species of the same genus. The wood of the bread-fruit is used for some purposes by the Fijians, but it is not so good as that of "Jack" (*Artocarpus integrifolia*) or the *artocarpus hirsuta*. It is soft, light brown, with parallel veins of a reddish colour. When wounded, the trees yield a large quantity of white sticky juice, which is used for caulking the seams of canoes. The tree is propagated by suckers attached to a portion of the root from which the sucker has sprung. The young trees grow rapidly, and in the third or fourth year, after planting, they reach a height of about 16 feet, and begin to bear fruit. They have a picturesque appearance peculiar to themselves, of which a minute description would convey a very indistinct idea.

The bread-fruit tree (*Artocarpus incisa*) is one of the valuable indigenous productions of the Island of Tahiti; and as it bears at various periods in different parts of the island, the fruit can be procured during the whole year. There is also a variety with seeds, called by a distinct name which I have seen at Erromanga (New Hebrides group), and it is also found at the Navigators' and Marquesas Islands. The *Artocarpus* delights in rich, moist, and sheltered situations, and is not found on elevated lands. The general name for the bread-fruit tree is *Maio*, there are twenty-four varieties.* A white viscid juice is collected by incisions from the trunk, which is an excellent substitute for pitch. This tree attains the height of from 50 to 60, and a circumference of 6 feet. The timber is excellent and durable, and is used by the natives for building their vessels, as well as for other purposes; its colour is reddish-brown becoming darker with age; the sap-wood is light yellow. Some of the native cloth (named *Hobu* and *Aone*) is manufactured from the bark of this tree, after undergoing the same preparation as the bark of the *Auté*, or Paper Mulberry (*Broussonetia papyrifera*): this latter plant is a shrub, from the inner bark of which the Polynesian Islanders manufacture their primitive cloth: the Japanese are said to use it in the fabrication of paper.

* 1. *Paeu*.—This is a mountain bread-fruit: the fruit is long, of a large size, and very rough or tuberculated.

2. *Rare*.—The fruit is round, with a bright epidermis.

3. *Maire*.—One of the best kinds: it is a large and round fruit, with rather a smooth skin, and the leaves are more divided than in any of the other varieties.

4. *Rautia*.

5. *Buaro*.

6. *Raumae*.

7. *Aravei*.—A long fruit with smooth skin.

9. *Poiakuri*.

10. *Tutara*.

11. *Piipia*.

12. *Iofai*.

13. *Fuara*.

14. *Ophia*.

15. *Ofatta*.

16. *Roru*.

17. *Oviri*.

18. *Olea*.

The fruits of these last-named eleven varieties are of large size.

19. *Pafara*.

20. *Afutu*.—Both these bear small and round fruit.

21. *Tao*.

22. *Pafai*.

23. *Annam*.

24. *Maiore maohi* (the common bread-fruit).—*Ceylon Observer*.

FIBRE PLANTS OF INDIA.

(By J. W. Minchin of Ootacamund, Madras Presidency.)

THE cultivation and treatment of fibre plants in India has occupied the attention of the Society of Arts on several occasions. The great botanist, Dr. Forbes Royle, first suggested the importance of the fibre-producing plants of India in 1854; and Dr. Forbes Watson, in an exhaustive paper before the Society, in 1860, enumerated the most important varieties; having, with the assistance of the Indian Government, collected specimens

and prepared plates representing them, which were published in the *Journal of the Society* (vol. viii, p. 448). Mr. Leonard Wray read a paper on Indian fibres in 1869, and it was again the subject of an article by Mr. P. L. Simmonds, in 1873.

Notwithstanding these frequent discussions and the thorough knowledge that has been obtained of the value of the different principal Indian fibres, and of their cultivation and production, there has been no great commercial movement in the export of these fibres, and this is due to the difficulty that has been encountered in the treatment; the cost of preparing the fibre for market by the native method of hand-scraping being prohibitive, and no machines or process for the economical preparation on a large scale having, until lately, been introduced.

For the valuable fibres strength and brightness of colour are essential. The ordinary process of retting or fermentation in stagnant water cannot be followed.

The *corchow*, or jute fibre, is used principally for coarse bags, and such purposes where the strength and colour of the fibre is not important. It can be produced at a very cheap cost; the cultivation of an acre of jute is estimated at Rs. 16 for the labour, and about half-a-ton of fibre is the usual crop; while by the retting process, one man can prepare for market about two cwt. of fibre in the day. The cultivation of jute has been taken up largely by the natives in India. The export stated by Dr. Forbes Watson in his tables, in 1860, at 88,000,000 lbs., had amounted in 1874 to 560,000,000, or seven-fold in the fourteen years. For the more valuable fibres this retting process is not available; a man can prepare only 5 lbs. to 12 lbs. of ree or Manila hemp fibre in a day by hand-scraping, while the waste is enormous.

The necessity for some mechanical treatment has been long recognised. In 1872, the Government of India offered a reward of £5,000 for any machine that could separate ree fibre in a green state, at a cost not exceeding £15 per ton. The conditions were not fulfilled, but a reward of £1,500 was given to Messrs. Greig, for relatively good results. The reward has since been withdrawn. The cultivation of ree has now been successfully introduced into the South of France, Algeria, and the Southern States of America; and the attention of scientific men to some chemical or mechanical treatment has been continued.

There are now two machines and two processes that claim to treat green fibre successfully. This being accomplished, the golden hopes of Dr. Forbes Royle and of Dr. Forbes Watson, as to the future of Indian fibre, may be realised.

As the soil and climate of the hill districts of Southern India and Ceylon, with which I have been connected for the past twenty-five years, seem to me to be specially adapted to the cultivation of fibre plants, and as the introduction of any new industry is at the present time urgently wanted by the European planters settled in those portions of our Eastern Empire, I have ventured to bring the subject forward again, for the purpose of urging the adaptability of this cultivation to the circumstances of the hill planters; and the fact that lately invented chemical and mechanical processes have supplied the economical and commercial prospects of success which have so long been desired.

The following fibre plants are suitable for cultivation in the hill districts of Southern India:—*Rhea* (*Urtica utilis*) Neigherry nettle (*Urtica heterophylla*)—these are dicotyledons, or exogenous plants, the fibres residing in their bark or bast—plantain (*Musa paradisiaca*), wild plantain; *Manilla* hemp (*Musa textilis*), also (*Agave Americana*), pine-apple (*Bromelia ananas*), wild pine-apple (*Bromelia sylvestris*), mooga, or bow-string hemp (*Sesuviera zeylanica*), nudar (or *Calatropis gigantea*)—which are monocotyledons or endogenous plants, the fibres being embedded in the pulp of their roots, stems, and leaves. These, and other kindred plants are indigenous to India, and can be cultivated without difficulty.

Rhea (*Urtica utilis*), *Boehmeria nivea* remia—China grass—is a perennial plant. In China, fields of ree are said to last, with care and manure, for 80 to 100 years. It grows in Sikkim and Nepal at an altitude of 3,000 feet. It has been cultivated successfully on many coffee estates in India and Ceylon; but it requires rich unexhausted soil. It grows with the greatest vigour in damp warm climates. In the islands of the Indian Archipelago it is cultivated under shade. It requires a light but fertile soil, but it must be well drained. It is propagated from the separated roots, from layers, slips, or cuttings; in this way five cuttings of grown stems can be expected in the year after planting; from seed no crop can be expected before the third year.

M. Favier describes the plant as giving out several stems, of which the number increases in proportion to the development of the root, which forms a kind of tuft or bush. The stems are woody, and have the appearance of thick strong rods, the highest varying from 5 to 12 feet. The roots, slips, or layers should be planted 18 inches apart, and after the first crop the alternate rows should be transplanted into new fields, leaving the remainder, about 3,500 plants per acre, to spread and cover the ground. The yield in Java is said to be 44 stems per year from each stool, taken in four cuttings. Each stem in its green state weighs about 1 lb.; 100 lbs. weight of green stems yields 5 lbs. of a raw fibre or filament, which by Muspratt's analysis, as quoted by M. Favier, contains 66 per cent of pure cellulose. In the official reports to the India Office, with native hand treatment, the crop is said to be 1,000 lbs. of raw fibre per acre, taken in four cuttings. M. Favier states that, in Algeria, 1,400 lbs. of fibrous stems was the crop per acre, as calculated by Mr. Hardy, ex-Director of the Botanical Gardens there, while in the South of France as much as 1,800 lbs. of filament have been obtained to the acre.

Mr. P. L. Simmonds, in his article in 1873 (*Journal*, vol. xxi, p. 762), stated that the crop gathered in Jamaica amounted to 300 lbs. per acre at each cutting, and that there had been five cuttings in the year, making the yield three-fourths of a ton per acre per year. While Mr. Bainbridge, in the discussion on Mr.

L. Wray's paper, in 1869, stated that the result of his own experiment in Assam was 750 lbs. green nettles, which gave 45 lbs. weight of fibre in each of three cuttings, making only 135 lbs. per acre per year (*Journal*, vol. xix., p. 453). The yield appears to depend on soil, climate, and treatment. The properties of the rhea fibre place it in the first position among vegetable fibres; it is second to none in strength, while the fineness or attenuation of the fibre places it before flax, and it is equalled only by the pine-apple fibre. It can be used for any textile purpose, having been mixed with cotton, wool, and silk, to advantage; it is in special demand for sailcloth, table napery, curtains and tapestry; but from the very limited supply as yet available, the applications of this beautiful fibre are yet in their infancy.

Neigherry nettle (*Urtica heterophylla*) is an annual, and can be readily grown from seed, giving its crop in about seven months. It gives a strong white glossy fibre, and a sample, hand-cleaned, was valued at £125 per ton. The cultivation has not been tried on a commercial scale: the difficulty will be in the cultivation and collection of the crop, as the leaves and stems are armed with a most poisonous sting. It has occupied the attention of planters on the hills for many years past, but no means of treatment was known.

Plantain (*Musa paradisiaca*) is generally cultivated for its fruit; it should be planted about six feet apart, and each stem will give about 4 lbs. of raw fibre, and 50 lbs. of fruit per year. The fibre is fine, white, and silky; long, light, and strong. The quality depends on the mode of cultivation and treatment; but it is not so valuable as Manilla hemp. The Government of India have constantly urged the value of this material for paper-making; but no use has ever been made of the millions of trees grown in India for their fruit. The stems are cut down, and left after the fruit is moved.

Manilla hemp (*Musa sylvestris*) has been successfully grown in Wynand and other hill districts, since 1864; but hitherto to no commercial value, from inability to treat the fibre. It is grown extensively in Manilla, where 250,000 acres are planted with this staple; it has hitherto been treated only by hand, the natives preparing about 12 lbs. weight of fibre per day, and receiving one-half its value for the work, the waste being so great that only about 1 lb. of fibre is obtained from each tree. Yet notwithstanding this, the exports have amounted to 35,000 tons annually. Manilla hemp is imported into Europe and America for rope-making only, and is worth £20 to £30 per ton, according to quality; the crop may be taken at from 10 cwt. to 2 tons per acre, according to successful treatment.

Aloe (*Agave Americana*) will thrive on any sterile waste land, and is now common throughout India. The cultivation is being extensively carried on in Mexico, where 5,000 plants may be found in an acre. It comes to full growth in three years, and can easily be propagated from suckers. The fibre is principally used for mixture with Manilla hemp in the manufacture of cordage, and is worth about £10 per ton less than Manilla hemp.

Pine-apple (*Bromelia ananas* and *Bromelia sylvestris*) produce a very valuable fibre. The former is cultivated for its fruit in all coffee estates, and the latter is found in large quantities in all the jungle swamps in the hill districts. The fibre is valued at £45 to £55 per ton.

Bow-string hemp (*Sansiviera tayloriana*) can be propagated on almost any soil, from the slips which issue in great abundance from the roots; it is perennial; the wild leaves are from 12 to 16 inches long, but under cultivation attain 3 to 4 feet. Dr. Roxburgh estimated that an acre of land would produce three-fourths of a ton of clean fibre.

Madar tam, serum (*Calotropis gigantea*) is common on all waste places in India. Mr. G. W. Strettel, of the Indian Forest Department, in his pamphlet, "A New Source of Revenue for India," published in 1878, urges the value of this product on the attention of the Indian Government. It comes to maturity in a year, is perennial, and requires no care. Mr. Strettel estimates the cost of bringing an acre into cultivation, planting four feet apart, at £29s. 8d., after which the only recurring expenses would be for harvesting and treatment. He estimates that it will yield a crop of from five to seven hundredweight per acre yearly, and the fibre is pronounced equal to good flax, and therefore worth £40 to 50 per ton.

The treatment of green fibre has now been successfully accomplished by the following machines and processes:—

The machine of Messrs. Death and Ellwood, of which over one thousand are now in use, for extracting fibre from all kinds of aloes, plantains, and pine-apple, &c., in Mauritius, Canary Islands, Africa, &c. It is almost the only machine in use for extracting Henquin fibre or Sisal hemp, and little or wild pine-apple fibre, in Central America, of which 17,000,000 lbs. weight are now exported annually. It is being tried in Manilla for the treatment of Manilla hemp. The jet of water which acts as an elastic cushion on which the fibre is beaten, to clear it of boon and useless particles, nothing else most satisfactorily in removing the gummy matter which causes the principal difficulty in the treatment.

2. An ingenious invention of M. Roquet, a Frenchman, for crushing and scutching vegetable fibres at one operation, which has been patented by Mr. W. M. Adams in this country and elsewhere. It treats all kinds of dry fibres most thoroughly, and has also successfully treated green rhea fibre from Kew Gardens.

3. M. Favier, a Frenchman, has suggested a process of treatment for rhea fibre, by steaming the green stems in the field. This enables the easy decortication of the bast by cheap hand labour, at a very small expense, and saves the cost of carriage of the woody portion of the stems, these being used for the fuel of the boiler that creates the steam. The stem ashes can be at once returned to the field as manure, together with the leaves and waste, so that only the fibre itself is removed from the soil; by

this process it is calculated that the fibre thongs can be obtained at a cost of 30s. per ton.

4. The process which is known as Ekman's patent, for the manufacture of cellulose or ultimate fibre from raw fibres, by treatment with the bisulphite of magnesia. This process consists in boiling the fibrous substance under a pressure of 90 lbs. of steam, in water containing sulphurous acid, in combination with sufficient magnesia to prevent the oxidation of the organic matter. This chemical treatment produces an ultimate fibre from the rhea plant, which is worth £168 per ton, or three times the value of the best cotton.

Seeing that it takes 100 lbs. of green rhea stems to make 5 lbs. of raw fibre or filament, worth at the rate of £45 per ton in the English market, M. Favier's steaming process, which saves the carriage of the woody portion further than the field in which it is grown, is an economical consideration of the highest importance.

This raw fibre or filament, after treatment in M. Ekman's boilers, is reduced from 5 lbs., worth at the rate of £45 per ton, to 8½ lbs. of ultimate fibre, worth £168 per ton. When this process is undertaken by the grower in India, as soon as possible after cutting and decortication in the field, the fibre is saved from the damage that is constantly going on from fermentation, as long as the tannic gum is attached to it; it being impossible thoroughly to dry the fibre while this gum remains. There is no trouble in at once drying and packing the ultimate fibre. The cost of carriage to the manufacturing market is reduced to a minimum, and the pure fibre is in no way damaged by pressure in packing under screw or hydraulic press. At the same time the cultivator obtains the full manufacturing value, which is otherwise intercepted by the mill man, who scutch, comb, and prepare the fibre for textile uses.

It seems that for dicotyledons, or exogenous plants, such as rhea and Neigherry nettle, M. Favier's steaming process, in conjunction with M. Ekman's bi-sulphate of magnesia process, have attained the desired object, economical and thorough treatment.

For the monocotyledons, or endogenous plants, such as plantain, Manilla hemp, aloe, pine-apple, &c., the machines of Messrs. Death and Ellwood, or M. Roquet, are required. For the coarser fibre obtained from these plants, no further treatment is necessary; these coarser fibres are used for rope-making. The finer fibres, such as those obtained from the *Bromelias*, and the selected finer portions from other kinds, may be advantageously treated in M. Ekman's boilers; while from the waste and inferior stuffs a paper pulp may be obtained which will be an important item in the receipts of the estate. In the cultivation of the fibre plants I have enumerated, the planters in the hill districts of South India will have varieties suited to every exigency of their soil and climate. For their exhausted fields, which are no longer suited for the cultivation of coffee, cinchona, or tea, there is aloe, mudar or moorga available, which will flourish on the poorest and most exposed hill-sides. For their low-lying rich valleys, at elevations too low for coffee or cinchona, such as the lower slopes of the Ghats, the cultivation of rhea fibre can be carried on; on the level land, where ploughing is possible, the Neigherry nettle can be sown to advantage. The undrained swamps can be planted with the *Bromelia sylvestris*, and the borders of the streams and steep forest hills can be cultivated with plantain and Manilla hemp.

The store houses and water-power generally found on the coffee estates that have been erected for the preparation of the coffee crops, and which are unused for nine months in the year, will supply the motive-power for the scutching machinery, and drying accommodation for the fibre. It is probable that the cost of Ekman's boiling and chemical process may be too considerable for each individual planter; but some convenient central factory established in each district, or on the coast, may enable the planters to obtain the benefit of this process, on the same principle as is now in use for the ultimate preparation of their coffee. It therefore seems that good hope is afforded that the cultivation of fibre plants may relieve the Indian and Ceylon coffee planters of much of the troubles that have befallen them, from the persistent attacks of the *Himoleia basistris*, or leaf disease.—*Journal of the Society of Arts*.

POULTRY-BREEDING—NATURAL AND ARTIFICIAL MEANS.

THE Asiatics, and also some other varieties, are sometimes troublesome in their disposition to sit. When they are so persistent in the matter, and it is desired to have them laying again, either of these two methods will be found efficacious: Put the hen in a box with a lath bottom—the laths not over an inch wide and two inches apart; the box a foot or more above the floor. Having no way of keeping her feet and breast warm, the feverish desire to sit is soon cooled off, and usually in three days she is ready again to be turned into the yard. Another remedy is to put the hen in a small pen, with no perches, and place with her a vigorous young cock, kept by himself for this purpose. Two or three days will usually effect the desired result.

Where the hens are to do the hatching, they need to be removed to the sitting-room. This should be done at night. Have the nest ready, with half a dozen nest eggs, and fixed with a cover. After dark, take the hen in a basket to the room, and gently place her on the nest, covering or shutting her in. Do not open the nest again until the next evening, then let her out, and give her food and water; after fifteen or twenty minutes, if she does not go on the nest herself, catch her and put her on, again shutting her in. This may need be repeated three or four days, but usually, unless the hen is nervous and wild, she will take to her nest of her own accord after the second day. When she does, then give her her eggs.

The French use turkeys for hatching, and in some places on quite a large scale. In some sections there are men who follow it as a business—hatching out chickens for the neighbouring farmers at "so much" apiece, or buying the eggs and selling the chickens as soon as old enough. One person in the vicinity of Lyons is said to have sixty turkeys sitting in the hatching season. Some years since I tried this method myself. It is not necessary that the turkeys should be broody; when wanted, they were caught, given a wineglassful of spirits, and placed on the nest with some dummy eggs under them. When they come out of their "drunk" they either imagine that they have legitimately begun their new business, or were so ashamed of their spree, rather than show themselves to their mates they prefer to remain in seclusion. These turkeys are kept sitting from two to three months; as fast as the chicks hatch, they are taken from the nests and fresh eggs placed under the turkeys for another clutch. Twenty eggs is the usual clutch given an ordinary sized turkey.

This same system of re-setting may be profitably pursued with hens. Where sitters are scarce, a good, quiet hen may be made to bring out two, and frequently three clutches. Care, however, must be had to keep hens and nests scrupulously clean, and have them come off regularly once a day for feed and water. In one case, which was an experiment, I kept a hen setting for thirteen consecutive weeks, bringing off four clutches of chickens, and I did not find that she was any the worse for her long period of incubation.

Another saving of time and expense, for which we are indebted to the French, is the use of capons to take care of the chicks after hatching. The capons are placed in a room or pen, without any perches, a week or two before they are needed. This accustoms them to squat on the floor or ground instead of roosting. At night one of them is removed to a small coop, and as soon as he gets quiet a few chickens are placed under him. The next day others are given to him, and they frequently have the care of twenty-five to thirty chickens, which they hover and tend as carefully as their natural mother.

It is hardly necessary for me to refer to the practice of doubling up broods, and I will merely state that among those who raise poultry for market it is customary to sit several hens at the same time and give the whole hatch to one hen, re-setting the others. I have seen this done on the Metropolitan Hotel farm to a greater extent than I know of elsewhere. An old Scotchman and his wife had charge of the poultry there, giving their whole time to it. I have seen broods of sixty to eighty chickens with one hen in May and the warm months. Seventeen acres were here inclosed and devoted to poultry. The yearly product was about three thousand chickens, three hundred to five hundred turkeys, and nearly the latter number of ducks. The laying and breeding stock, as well as the growing chicks, were fed largely upon the scraps from the hotel-table, which were barreled and sent up twice each week.

Thus far we have treated this subject purely in its natural light, or rather as we pursue it unassisted by any mechanical appliances.

In treating it as followed by artificial means or methods, it is perhaps best to digress a few moments from the subject proper and consider briefly what the artificial methods are; for, strictly speaking, there are two methods of hatching artificially: One, in which the eggs are subjected to heat all around, above and below, *i. e.*, enveloped; and the other, to only a top or contact heat—the same as given by the hen. We might term the two systems in contra-distinction the first, an enveloping heat; the second, a top heat. This heat may be communicated by hot water, steam, or a current of hot air passing over or through the egg-chamber, or by imbedding in a manure pile; all seem to be efficacious—though in unequal degrees—provided the temperature is kept up. But it is here where the method of "enveloping" heat fails; my own experiments with this method—and which are corroborated by those of English experimenters—is, that the only temperature which will give good results is 104 degrees Fahrenheit, and this heat must be maintained steadily throughout the three weeks of incubation.

The difficulty of keeping such a uniform temperature in a climate like ours is manifest; except with the almost constant watchfulness of an attendant, it would be next to impossible.

With the other method—top heat by radiation—a daily variation of from two to three degrees is not injurious, provided the eggs are turned regularly, and properly handled. In fact, an occasional variation of even five degrees is not necessarily hurtful, though in the early stages of incubation it had best be avoided. I advise a daily variation of not over three degrees, except of course the lowering of the temperature while the eggs are being aired and turned.

This top, or contact, heat is the nearest imitation to the natural process. Take, for instance, the hen or fowl making her nest on the ground, the top of the eggs, when in contact with her breast, are kept at the required heat; while the bottoms of the eggs resting on the ground must be many degrees colder. So, also, with the nests of birds: the nest is open and admits almost free circulation of air to the bottom of the eggs, while the top is kept warm by the mother bird. Such being the case, is it not reasonable to suppose that the top-heat system should give better results than the placing of the eggs in a warm bath—as it were—which is the case in all methods or machines when the heat is applied under or around the eggs? My experiments in this direction have been frequent and exhaustive, and cost me many hundreds of eggs as well as disappointments; but I can only regard the experience as cheaply gained, now that I have obtained such a high degree of success.

When we consider the process of incubation, the reason for following natural methods are very plain. We cannot hope to improve upon her ways of creating and developing animal life, and our best way is to imitate her as closely as possible.

It is well known to most breeders, and probably to many of my hearers, that the germ or life-giving principle of the egg always floats on the top. Under the influence of the heat the arteries and veins expand and extend, following the outside of the white of the egg until they reach completely around the yolk. The extremities

of these veins are very fine and delicate. Nature, in her wise provision for the best development of their growth insures the bottom of the egg, where these fine veins are, being kept rather colder than the top, the contact of the body of the mother-bird with her eggs heating the top of the eggs, and keeping that portion several degrees warmer than the bottom.

When, therefore, the heat is applied under, or all around, the egg, these minute veins, instead of growing, shrivel and dry up; the yolk sack, instead of being absorbed by the growing chick, dries fast to the shell, and about the fifteenth or sixteenth day the chick dies. Some may reach the twentieth day, and few may, and do sometimes, hatch out; but the percentage is so very small that it virtually amounts to a failure.

The next point to insure success is the turning of the eggs. The hen usually makes her nest slightly hollowing, and when sitting thrusts her feet below the eggs. At intervals she raises one foot, which motion causes all the eggs on that side to roll down a little toward the centre of the nest; then she raises the other, and the eggs on that side are moved. By this simple action the eggs are moved in position as well as turned; she will also, with her beak, move the eggs from the centre of the nest to the outside. Instinct, or nature, whichever you may choose to call it, teaches her that the eggs under her breast receive a greater degree of heat than those under her wings or on the outer edge of the nest; and that to succeed in her maternal efforts, she must give all the eggs in turn the benefit of the greater heat. In doing this the eggs are turned; and whether it is called turning the egg, or something else, the effect is the same. To test this matter I have several times carried eggs through the whole three weeks in the incubator without turning or moving them at all. Unless some accident interfered there were some which hatched—generally from thirty to forty per cent.; others which pipped the shell, but had not strength enough to get out, and still others, dead, with the yolk sack not fully absorbed, and dried fast to the bottom of the shell. Of those which did hatch, most were weakly, and full one-half died before they were a week old. One lot which I turned twice a week did ten or fifteen per cent. better. Another, which was turned daily, hatched seventy per cent.; and a final test when I turned the eggs twice daily, I obtained fifty-eight strong healthy chickens out of sixty fertile eggs, and both the remaining eggs had fully developed chicks in them.

Hence I adopt the practice of turning twice daily—morning and night.

Further experiment—turning them three or four times a day—has not given any better than this.

We may now consider the practical application, or use of artificial incubators. Most persons, even among those who yearly have raised large numbers of poultry, have treated it as an amusement for the fancier or gentleman farmer who might perchance manage to hatch a few puny, sickly chicks at a sacrifice of dozens of eggs. That this has often been the case with incubators is but too true; but the great improvements of the past few years make such a result among the things that may only possibly occur by carelessness or negligence.

We have an incubator which, with fifteen minutes' attention, morning and evening, any intelligent person can certainly hatch from seventy-five to eighty-five per cent. of the fertile eggs.

It is unnecessary to assume what gain this would be over the natural way, for it is well known to every one who has had any experience in this line, that the average result among the farmers and breeders of poultry for market will not nearly reach that figure.

Take, for instance, one hundred eggs to be hatched in the natural way; these would require eight hens to cover. Of these eight, one would desert her nest before her brood was due, two more would each break one-third of their eggs, and the remainder average ten chicks to a sitting; or, say, a total of sixty chicks from the one hundred eggs.

This, as many of you well know, is a good average result. It too frequently happens that the hen will become apparently in the condition of the herd of swine mentioned in the Holy Writ—possessed of devils—and conspire to break all the eggs they possibly can, and then leave all they could not break to chill and die.

I know of one such case, the past season, where a neighbour secured from eleven hens a single brood of eleven chickens—an unusual result, you say; but one such result cuts down the year's percentage far below my figures, and thus proves my assumption.

And now, to one summary of the two methods:

Assuming that we wish to turn out four hundred chickens per week for ten months of the year, which would give us about seventeen thousand in all. We would need for this three incubators of five hundred eggs' capacity each. Those of the pattern on exhibition at the poultry exhibition—the new Centennial—would cost one hundred dollars each. I would also add one of the small size, one hundred eggs' capacity, as an auxiliary, costing forty dollars, making the total cost of incubators three hundred and forty dollars.

You will please bear in mind that I am allowing for a loss of twenty per cent. of the eggs, which is fully five per cent. more than the average loss with this machine.

To keep these machines stocked with eggs to their full capacity will require five hundred per week. Taking the season through the average hen will not lay oftener than three days out of seven—hardly that; yet we will assume that as our average—hence, for every three eggs we get we must keep seven hens. At this rate we shall need about 1,150 (actual number is 1,148) hens to keep the machines stocked, which, at fifty cents each (a very low figure, as you poultry-breeders all know) will cost \$575.

Our outlay, therefore, so far amounts to \$916.

Now, as to the number regarded by the natural method and the cost.

First, we must allow for a loss of forty per cent. of the eggs under this method. After twenty-five years' experience and observation, I feel satisfied that nine-tenths of our farmers will exceed that per cent. of loss rather than come below it.

We shall require, on the same rates as computed above, 1,540 hens for our laying stock alone to produce six hundred and sixty eggs weekly—the number required. To cover these, allowing thirteen eggs per hen, will require fifty hens per week for three weeks, one hundred and fifty in all. Now, allow that we double broods when hatched and reset half the hens, and we must have twenty-five hens more for the fourth, fifth, and sixth weeks, and each succeeding week after.

Allow also six weeks as the time each hen runs with her brood, and then immediately commences to lay again. We are constantly losing with every hen a laying period of nine weeks out of the season, which, estimated at forty-two weeks, is three-fourteenths of her time.

To compensate for this we must add 330 more hens to our flock, making 1,870 in all, which, at fifty cents each, the same as above estimated, makes \$935 as the outlay by the natural method as against \$915 by the artificial, a clear gain of \$20 in cash in favour of the latter, without taking into account the trouble of obtaining your sitters just when wanted.

As most of us know, when we have an abundance of eggs, we have few sitters, and when we have plenty of sitters, eggs are often scarce. With the use of incubators we have no difficulty from this source, our "sitters" being always ready.

Our next comparison is as to cost of hatching. First, we will consider the size of room required to cost the same in either case, although in reality the space required for one hundred and fifty sitting hens will be double or treble than needed for four incubators.

The nests for the hens, at a low estimate of ten cents each, will amount to fifteen dollars; straw or hay for the nests for the season, say, five dollars more; next food. It is computed that one dollar will keep a hen a year, i. e., when she is running out and has access to worms, grubs, &c., which in this case she has not, and I do not think in that view of it that one dollar per head is too much to charge for the ten months; say, one hundred and fifty dollars for feed, plus twenty dollars for nests and litter, equals one hundred and seventy dollars. The matter of attendance is a difficult item to get at, and we will leave it for the present.

Now our machines will burn, say, ten gallons of oil per week; this is allowing three gallons for each of the larger machines and one gallon for the small machine. (I think this an over-estimate.) At sixteen cents per gallon, which is the average price in New York market, this will cost us for forty-two weeks, \$87.20; wicks and possibly new burners, \$4.80 more. Add also interest on the cost of our machines at six per cent. (seventeen dollars), and we have a total of eighty-nine dollars—call it ninety dollars even money, which, taken from one hundred and seventy dollars, leaves eighty dollars—a gain in favour of the machines.

Next comes the question of care or attendance, which we cannot estimate, although it is very evident that the care of one hundred and fifty hens must be double that of four incubators.

The next cost to be considered is the coops or brooders for the chicks. If we follow the artificial system exclusively, we shall need brooder accommodations for four hundred chicks weekly, which will cost us for three brooders. No. 4 size, four hundred chicks each complete, say, thirty-five dollars—one hundred and five dollars. To these we must add three summer mothers, at ten dollars each, making \$135.

In coops, if we use hens as brooders, we shall need twenty-five each week for six weeks, making one hundred and fifty coops, allowing \$1.25 (which is twenty-five cents less than I have ever been able to get them made for), and we have a cost for coops of \$187.50—another balance of \$52.50 in favour of the artificial method.

The cost of oil for the brooders will not be any more, and probably hardly as much as the food for the hens while cooped with the chickens.

We have thus far figured a clear gain of \$152.50 in favour of the artificial method, giving the hens the benefit of the estimate in every case.

Next we must consider the great gain derived from the increased number of chickens raised under the artificial system over the natural one.

This is computed by breeders, who have tried both, to be fully ten per cent. Hatched artificially, the chicks are free from lice, for there is nothing from which they can be communicated. And as lice and mites are without doubt the cause either directly or indirectly of fully two-thirds of our poultry ailments, it follows that our young stock is healthier, more thrifty and growthy, and we are enabled to raise a much larger per cent. than with the hens.

Another gain, and one that commends itself to every breeder of poultry, whether for fancy or for the market, is the advantage of always being able to sit the eggs while they are fresh, whether it be in midwinter or midsummer.

This waiting for broody hens while your eggs are spoiling is a source of great annoyance as well as much pecuniary loss to the breeder, and should be a strong argument in favour of his adopting the artificial method.

Another advantage (which, while not a pecuniary one, is of great satisfaction to the fancier), is the resulting gentleness of the young stock. Even the natural timidity of the Leghorns and Hamburgs—the meekness of our domestic breeds—is overcome, and the chicks take food from the hand, and perch on the shoulder of the feeder, with an entire absence of fear. This has many advantages, which are quick to be appreciated, especially by ladies who have the care of chickens.

We estimate that to produce and rear a chicken by artificial means to eight weeks old, costs an average of fifteen cents each.

This is in the vicinity of New York; in the West, where grain is cheaper, it will cost somewhat less.

I speak especially of this age—eight weeks—because it does not pay us in the East to raise them to adult age. At this age they are worth for broilers from fifty to seventy-five cents each; for every week over that age the cost is increasing at a much greater ratio, and the price is either stationary or decreased.—*Thoroughbred Stock Journal*.

MATE OR PARAGUAY TEA.

THE following account of the Paraguay tea plant is taken from a translation published in the *Pharmaceutical Journal* of a paper by Dr. Theodore Peckolt in the *Zeitschrift d. allg. öster. Appt.-Vereln*.—

This plant, which belongs to the holly family (*Illicaceae*), has several names in different parts of South America. In the Guarani language it is called *Cad*, which is the Indian word for leaf. The prepared leaves were named by the Spanish "yerba" (herb), and the infusion "mate" [unaccented] from the native name of the vessel in which the tea is made, and the drug is now generally known as mate in Brazilian commerce, although the Spaniards call it "yerva mate" or "yerva de palo." The name "coughoha" has been said by some writers to be applied to mate, but this is an error, for the Brazilians understand by the names "coughoha mansa" and "coughoha brava," other trees belonging to the same natural order, which are used as a substitute for mate when it is not easily procurable.

The plant was first briefly described by St. Hilaire, in 1822, when he gave to it the name *Ilex paraguayensis*, which he altered in 1826, to *Ilex Mate*, subsequently publishing the first name again in 1833, and this is now adopted in the "Flora Brasiliensis." In 1824 the plant was described in detail by Lambert, under the name of *I. paraguensis*, and the plant illustrated from specimens from the Jesuit Missions. The synonyms stand as follow:—

Ilex paraguayensis, St. Hil.; *I. Mate*, St. Hil.; *I. paraguayensis*, Hooker fil.; *I. paraguensis*, D. Don; *I. paraguensis*, a, obtusifolia, Mart.; *B. acutifolia*, Mart.; *Cassine Gougonha*, Baben; *O. Gougonha*, Guibourt; *Chomelia amara*, Vell.

The mate plant attains the height of an apple tree, becoming even larger in favourable situations, but when cultivated and deprived from time to time of its leaves, it remains small and forms a more bush. The leaves are shortly stalked, simple, wedge-shaped, obovate or elongate-lanceolate, toothed, dark green above, paler beneath, shining, of leathery consistence, one to three inches long, one-eighth to one-and-a-half inch broad. The flowers are axillary, situated on one to three times forked peduncles, white, and of similar size to those of the common holly. The ovary consists of four nearly orbicular sepals with a four-parted corolla and four short stamens, the ovary being crowned with a four-lobed stigma. The fruit is red, and of the size of a pepper-corn, containing four seeds enclosed in slightly glutinous pulp, but often one seed only is developed. The home of the Paraguay Tea Plant is said by Martius to lie between 18° and 30° S. latitude, but the district in which the tree grows most luxuriantly is between 21° and 24° S. latitude in the watershed of the Paraguay river on the west, and in that of the Paraná river on the east, and it is here in a zone between the Serra Anambuy on the South, and the Serra Marajoit on the north, that the best and most highly prized mate is prepared.

How long the South American Indians had been in the habit of using mate is not known, but when the Spaniards seized the provinces on the rivers Paraguay and Uruguay they found this custom prevailing there exactly as first mentioned in the writings of Azara, who stated that the tree grew wild in different parts of Paraguay. In proof of the high estimation in which it was held by the Indians, it may be mentioned that the name "caá," which signifies in the Tupi language a tree or plant, was given by way of distinction to mate, that being the tree valued above all others. The use of mate does not appear, however, to have extended to extra-tropical districts, but to have been confined to the more intelligent tribes known now under the name of Guarani Indians. Nevertheless, when these people were driven further north by Karipounas, they do not appear to have carried the use of the drug with them, probably thinking it not worth while to obtain it from a distance and from a hostile people, when they found a substitute close at hand in the Guarana plant.

The extensive use of mate in South America at the present time is probably due in great measure to the Jesuits, who encouraged its use, finding that it restrained the desire of the Indians for spirituous drinks, while its cultivation, collection, and preparation gave employment to converted Indians, and brought wealth to the Order. In the Jesuit Republic, the Indians were not paid in money but in produce; 4 lbs. of mate were allowed to each family.

After the expulsion of the Jesuits, the preparation of mate was continued in the Paraguay Republic under the administration of the Dictator Francia and his successors, until Dictator Solano Lopez was killed in battle with the Brazilians in 1870. An overseer was appointed over the work who also was paid in kind, receiving for each arroba of the tea, natural produce of the value of 1 ounce of gold. Since 1870 there has been free trade in the article, which renders an increase of the trade very desirable. At the present time mate is used by about 12,000 of people, and the consumption amounts to about 8,000,000 pounds.

It has been stated that mate is not prepared solely from *I. paraguayensis*, St. Hil., but that the leaves of other species are mixed with it.

In 1842, Sir W. J. Hooker published, in the *London Journal of Botany* (vol. i., p. 30), an exhaustive account of the yerba mate, together with the characteristics of the different

varieties which he considered identical with *Ilex paraguariensis*. This paper strengthened the previous opinion of Miers that probably more than one species was used in the preparation of the tea. The investigations made by Miers and the monk Leandro, Director of the Botanical Gardens in Rio Janeiro, confirmed by Bonpland, indicate that six different species are used for the purpose:—(1) *Ilex theezans*, Bonpl., growing in Paraguay, Entre Rios, and Brazil; (2) *Ilex ovalifolia*, growing in the neighbourhood of Rio Pardo; (3) *Ilex amara*, Bonpl., on the mountains of Santa Cruz, and in the forests of the Brazilian province of Parana; (4) *Ilex crepitans*, Bonpl., in the interior of Santa Cruz, and the banks of the Parana river; (5) *Ilex gigantea*, Bonpl., on the banks of the Parana river. This is the "cauna" of the Guarania. (6) *Ilex Humboldtiana*, Bonpl., in the province of Rio Grande do Sul. This is the "cauna-una" of the Brazilians. The last four species, more especially *I. amara*, yield the "ca-chira" of the Guarania and the "cauna" of the Brazilians. Martins, however, in the "Flora of Brazil," states that in the central districts of Paraguay, where the *I. paraguariensis* is especially abundant, only the leaves of the species are used; in other districts the various species of *Ilex* are similarly employed.

It is certain, however, that *I. paraguariensis* is the only species in cultivation, but this is carried on to a very limited extent as the wild plant is still abundant. The Jesuits planted the tree because they found that under cultivation the leaves had a milder and more pleasant taste. For cultivation, the seeds are carefully freed by washing from the glutinous matter in which they are imbedded, without which treatment they would not germinate, this office being probably performed in a natural state by birds, since the Indians believe that the seeds will not germinate unless they have been voided by birds. The young plants are taken out of the hot-bed when about six inches high, and planted out about twelve or fourteen feet apart, in a damp, somewhat marshy ground, so as to allow of a small trench being made around the plants in which water can collect. They must also be grown under the trees which afford shade, as the young plants are easily killed by a strong sun. When they are about three to six feet high, some of the shade plants are removed, and in four years the leaf harvest can be begun. The young trees should not, however, be entirely deprived of their leaves, lest they should not be able to recover. In the seventh year they will yield thirty to forty kilos of leaves. It is calculated that on 220 square metres of land one thousand six hundred trees can be grown, yielding on an average thirty-five kilos of leaves per tree, or about 25,454 kilos of leaves, valued at 190,000 marks per 100 square metres. The cultivated plant remains a small bush, and never reaches the stature or size of the wild tree. The cultivation of mate has been carried out with much success in the province of Parana by Dr. E. Westphalen, and it promises to be successful in the Dutch colony of S. Leopoldo in the province of Rio Grande do Sul, where the plant grows luxuriantly.

The tree has been planted in the Cape of Good Hope, and seems to succeed well there, as well as in Spain and Portugal. The quality of Paraguay tea depends upon the time of year in which it is collected, the leaves possessing most aroma when the fruit is nearly ripe. In the Argentine Republic, and in the Brazilian province of Rio Grande do Sul, the leaves are collected from February to the end of July. The new shoots are put forth in August, but at that time it would ruin the trees to gather the leaves. In the forest of the Brazilian province of Parana and Santa Catharina, the harvest is collected from March to the end of September. In Paraguay it begins in December and continues till August. About a month beforehand the collectors set out in caravans with their wives and children into the forests where the mate trees are abundant, and make their encampment.

The first operation is to prepare a torrefier, which is made in the shape of an arbour. The twigs are cut off from the branches and slightly scorched by drawing them quickly across the fire. The twigs are then collected into bundles suspended over the torrefier a small fire of dried wood being kept alight beneath. In about two days the drying is completed, the ashes are removed, and in the spot where the fire was an ox-hide is spread out, on which the leaves are beaten from the twigs with a wooden blade. The dried leaves are then powdered and packed in wooden cases made of hollowed trunks of trees.

In the province of Parana the leaves have lately been dried in large wrought-iron pans, in the same manner as Chinese tea, or in specially constructed ovens in which they can be prepared so as to retain more aroma; they are then powdered by machinery and sifted; this kind of mate obtains a better price.

Another form in which the leaves are prepared is by carefully separating them from stalks and twigs and roasting them, but this is not so much esteemed as the powder except in Chili, where the leaves are prepared.

In the South American Republic and the Brazilian province of Rio Grande do Sul, mate is packed in serons of ox-hide holding thirty kilograms, and in half-serons, containing fifteen kilograms; this packing gives to the mate a disagreeable flavour, which detracts from its value.

In Parana it is packed in cane baskets; these are lined with dried grass, called Jacaga, and contain fifty to sixty kilograms. The mate in leaves is here sold at 280 to 290 reis (about fifty-six pence); powdered mate is sold in thick and better-woven cane baskets, containing in a half-seron fifteen, and as a seron, sixty kilograms, the price being ten to twelve per cent more than the leaves.

In the Spanish Republic three different sorts are sold under the following names:—

1st.—*Ca-cuy*, or *Ca-cuy*; these are the new leaves of the scarcely developed shoots. They are of more delicate texture,

and of a yellowish colour. They possess an agreeable and pleasant flavour, but are seldom met with in commerce.

2nd.—*Ca-mirim*.—This was the chief product in the time of the Jesuits, and consists of the leaves carefully separated from the twigs and stalks, the mid-rib of the leaf being also removed. This kind is chiefly esteemed in Peru, and principally exported there by the Brazilians. It is called *hera manca*.

3rd.—*Ca-guacu*, *Ca-una*, or *Yerva-de-Palo*, is the most inferior kind, consisting of the large and old leaves with the twigs and fragments of wood, and possessing a strong and bitter flavour.

In Rio Janeiro, two sorts are known to commerce—mate in leaf and mate in powder. In order to test the quality of mate, the merchant takes a small quantity in his hand and blows upon it. If the greater portion is blown away, he considers that it has been heated too much, and thus deprived of its strength. If it is not easily blown away, it is then considered of good quality.

Mate has been the subject of several analyses. In 1836, Trommsdorff analysed mate and found tannin, two resins, extractive matter, and a substance which he believed to be an alkaloid, but he possessed too little material for complete investigation.

In 1843, Stenhouse found in mate an alkaloid, and proved that it was identical with caffeine.

In 1850, Dr. Rochleder investigated Paraguay tea, and found the reactions of mate-tannic acid to be identical with those of coffeetanin acid.

Lenoble, who, as well as Dr. Rochleder, supposed mate to be produced by *Peorale glandulosa*, named the crystalline active principle he obtained from it, "peoralin." He also found in it wax, albumen, and volatile oil.

According to Dr. Byasson, mate contains as much caffeine as the best Chinese tea. The variety which he experimented upon was *ca-guacu*. He found also a viscid substance resembling birdlime, soluble in ether; this he considered to be a fatty body of the nature of a compound ether, whose alcohol was allied to cholesterol.

Robin has examined several different kinds of mate. The amount of caffeine in young leaves dried without special care was 0.02 to 0.03 per cent.

Mate prepared by the Indians, and containing twigs and fragments of fruit yielded 0.16 per cent, and mate from the mission of the province of Corrientes, 0.14 per cent. The peculiar tannic acid, which Dr. Byasson did not find, varies between 1 per cent and 1.6 per cent. The ash of young leaves varies from 0.12 to 0.2.

Professor A. W. Hofmann, of Berlin, found 0.3 per cent of caffeine. The average of the published analyses indicates about 1 per cent of caffeine, that of India tea being 2 per cent. The value of mate, as in the case of tea, depends not merely upon the caffeine but also upon the tannin and aromatic principles. He considered the tannin to be identical in every respect with that found in tea.

The aromatic principle has not been isolated, but by dry distillation a volatile oil is obtained, which belongs to the phenol group and is soluble in alcohol.

In 1877 the mate-tannic acid was examined by Dr. Pedro N. Arata, who found that the tannin of mate, while analogous to that of coffee, was not identical. The chief differences noticed by him are as follows:—Lime water gives with the coffee-tannic acid a small precipitate soluble in excess, but an abundant insoluble precipitate with the tannin of mate. This, however, does not hold good with all samples of mate, the precipitate being sometimes soluble in an excess of the tannin. Coffee-tannic acid gives by dry distillation pyrocatechin, while the tannin of mate yields in addition to pyrocatechin the isomeric body resorcin.

Coffee-tannic acid is soluble in 52.84 vol. of alcohol, while mate-tannic acid requires 73.66 vol.

Dr. Arata considers that coffee-tannic acid may be regarded as dioxyparacinnamyllic acid, whilst mate-tannic acid must be classed in the group of oxyphenylpropiolic acid.

Soubiran and Dulongre state that mate contains the same essential constituents as the coffee leaf, and in greater amount than the coffee seeds, which Dr. Peckott confirms after numerous experiments with large and small quantities.

KAING GRASS FOR PAPER-MAKING.

THE following communication on this subject from Mr. Henry Buckle, the Deputy Commissioner in British Burmah, has been addressed to the Editor of the Paper-Makers' Monthly Journal.

SIR,—I have lately read a letter from Mr. Listard, on the above subject, at page 352 of your Journal of 15th December last, and I think a further account from me may be acceptable.

Kaing grass, or, as it is sometimes called, "elephant grass," is a kind of reed which grows wild all over the southern portion of British Burmah. It reaches to a height of 12 to 15 feet, and growing luxuriantly in places where nothing else will flourish, there is little probability of the supply ever failing.

Under the orders of the Government of British Burmah, I have carried out three experiments with this grass, in order to decide the question whether it can be utilised for paper-making.

I should first note, that while convict labour was utilised in the vicinity of the jail, the grass had to be cut by free labour, since, if the convicts had been sent out, they might have taken the opportunity to escape.

The grass was cut down close to the ground, and carried in bundles to the jail. Inside the jail, convicts cut off the tops of the grass, where the cane comes, and the tops were discarded. The

canes were then stripped of the outer portion of barks and were generally cleaned. After being passed through a crushing mill they were cut into short lengths, the joints being thrown away. This was done because the fibre was found to be weakest at the joints.

The short lengths of cane, which were some ten inches long, were then carried outside the jail, and thrown into large wooden tubs, which were placed on a raft anchored in the river, on which a gang of convicts were working.

The convicts sat on the raft, each man having a block of wood in front of him, and was provided with a wooden mallet. A handful of canes was taken out of one of the tubs, was beaten on the block, and, being constantly immersed in water, the pithy matter was gradually got rid of.

The whole of the day's supply of the raw material having been thus treated, the tubs were filled with fresh water, and the stock—as I shall now call it—was left to soak all night.

In the morning this stock was first beaten once more and rinsed, and was then placed on a raised, open bamboo platform, for the water to drain off and for the fibre to dry. It was found that in drying the cane bleached it almost white. The stock was then stored in a shed to finish drying and to be packed. Under date 18th January 1882, the Bally Paper Mills reported as follows on a consignment of 3,690 lbs. of paper stock prepared in the way described:—

"This (45 maunds of stock) we boiled with caustic soda at 20 per cent, and bleached with bleaching powder at 15 per cent. The sample of the paper sent will show a fair result for a first trial. The colour does not come up particularly good. This may be improved. Under-boiling may have affected the colour. The stuff is very easily treated, washing freely. We have not been able to ascertain the loss in weight, but it is considerable."

Under dates 18th and 24th August 1882, the Bally Paper Mills reported as follows on a consignment of 400 lbs. of paper stock prepared as before:—

"The five bales were placed in the boilers without any previous cleaning, and boiled with 20 per cent of caustic soda for 10 hours. The boiling was next bleached with a solution of 15 per cent bleaching powder, after which it was passed through the breakers and beaters in the usual way, and finally on to the paper machine, over which it ran very nicely and cleanly."

"The trial was made under great disadvantages, owing chiefly to the very small quantity of material to be experimented with, and also to the fact that during the monsoon it is very difficult to obtain really clean water, so that the colour is not so good as might certainly be expected with clean water such as is obtainable from October to June."

"There is no doubt that this material is very suitable for paper, being easily wrought, and showing, as far as could be judged by this trial, that the loss in weight is less than that of any other grass experimented upon by the Bally Mills. The paper, too, is strong and clean, and shows an excellent surface."

"Colour.—We have not the slightest doubt that the material can be bleached up to a good white, and so be capable of taking any tinge desired."

"Strength is most satisfactory, and is great enough for almost any uses to which paper can be put, except for bank-notes and such-like."

"On the whole we are very pleased with the success of this trial, and feel convinced that if the material can be produced at a reasonable rate and in large quantities, it will soon make a name as a paper-making material."

"We should think an arrangement of fluted and plain rollers, with a free supply of water, driven either by water, steam, or manual power, would greatly tend to reduce the cost of cleaning."

Under date January, 1883, the Bally Paper Mills reported on a consignment of 50 baskets of the paper stock, containing over 3,000 lbs., which had been prepared in the same manner and with exactly the same care as the two former consignments. The words of the report are not quoted because they are contradictory, and because, less chemicals having been used—a solution of only 18 per cent caustic soda and 13 per cent bleaching powder—the unsatisfactory results is not conclusive.

Under date January, 1883, I received a report from a gentleman in England to whom I had sent a small quantity of the paper stock, prepared as described, and he said that he had experimented with my material and some *esparto* grass, and that, having used the same quantity of chemicals with each, mine was "the stronger of the two, and it certainly shows whiter."

Under date 23rd January, 1883, I received a report from a gentleman in Scotland, to whom about 70 lbs. of the paper stock, prepared as described, had been sent, and he wrote as follows:—

"As regards the respective advantage of *kaing* and *esparto*, there is no doubt that *kaing* makes a stronger paper than *esparto*, and that it also bleaches better. But it cannot be picked and cleaned so well as *esparto*."

"There is a kind of black bark, which is hardly noticeable before boiling and which will not bleach, which seemed to be present in considerable quantity in the sample tested. If this could be got rid of, *kaing* would be quite as clean as *esparto*."

"Another objection to *kaing* is that it is more bulky than *esparto*, not in the bales, but in the boilers: it swells up more than *esparto* and so much cannot be put in. The same applies to the breakers, potchers, and beaters, perhaps more at the beaters than elsewhere, as, while it takes a certain time and a certain amount of power to beat an engine containing a given weight of *esparto*, it takes the same time and the same amount of power to beat about two-thirds of the weight of *kaing*."

It will be noticed that all the reports agree in saying that the paper made from *kaing* grass is very strong, stronger than paper made from *esparto* grass.

As regards the colour, too, the reports are very favourable.

The black barks noticed by the gentleman in Scotland were also mentioned in the third report from Bally, but they were not very noticeable in the sample of the paper made which I received from Bally. No really fair table can be drawn up of the cost of the preparation of this paper stock, as convict labour was employed, and extra warders had to be engaged to look after the convicts working on the raft.

During four months I employed on an average 22 convicts a day, some inside the jail, and some on the raft. I worked up 47,136 lbs. of the canes, as cut and with the tops on them, which cost 48 rupees (24 16s.), into 6,761 lbs. prepared and dried paper stock.

The cost, therefore, of enough canes to make 140 lbs. of prepared and dried paper stock was 1 rupee.

With the 22 convicts I turned out each day about 70 lbs. of prepared and dried paper stock, so that 140 lbs. would represent about the outturn of two days' work of 22 convicts.

Following the usual calculation that one free man will do the work of two convicts, the cost of the preparation of 140 lbs. of prepared and dried paper stock would be somewhat as follows:—

| | Rs. |
|---|---------------|
| Cost of sufficient canes to make 140 lbs. of prepared and dried paper stock | 1 0 0 |
| Hire of 11 free labourers for two days, at 8 annas each per day | 11 0 0 |
| | Rupees 12 0 0 |

The cost, therefore, of 100 lbs. of prepared and dried paper stock would be Rs. 8 : 9 : 1, or 17s. 1d.

Knowing that *esparto* grass is shipped to England in its raw state, an experiment has been made in sending thither a considerable quantity of *kaing* grass tied up in bundles as cut. I have not seen any report of the result, but I have heard that the grass was found to have become quite brittle on its arrival in England, and to be quite useless.

If this material is to be brought into use for paper-making, some labour-saving machinery must be adopted to reduce the heavy cost of hand labour. It might perhaps be possible to utilise the splendid water power which is at hand in Burmah, or, if that is not possible, steam might be used, and there is at least good reason for hoping that a valuable coal deposit has been discovered only a few miles from the banks of the Irrawaddy river.

To anyone proposing to commence the preparation of paper stock from *kaing* grass on a large scale, I would suggest a site in the district of Thongwa in British Burmah, where *kaing* grass is to be found growing wild over large areas.

An arrangement might gradually be come to with the villagers to deliver the canes at the mill at a certain price. The canes might then be cut into lengths, discarding the joints by machinery, and then I believe the ordinary breakers and beaters would remove the pith and leave the pure fibre, which could be dried, pressed, and packed in bales for shipment.

Yours faithfully,
HENRY BUCKLE,
Deputy Commissioner, British Burmah.

IMPROVING FLOCKS.

THE merchant is constantly trying to improve his trade by improving the quality of his goods without increasing the price in proportion, trying to meet all the wants of his customers. The manufacturer tries to increase the amount of his sales and profits by improving the character of his manufactures; so, likewise, should the flock owner make it a constant study how to improve the character of his flock, both as to its capacity for increasing the weight of carcasses and wool from a given amount of food, and its capacity for breeding strong, healthy lambs. Every element of income should be taken into consideration, and an effort made to increase the value of each.

The best digestion produces the best growth of body from a given amount of food, and the power of digestion is increased in several ways. First by the proper selection of foods. A mixture of grasses is nature's prescription of food for the sheep, as well as other grass-eating animals. This mixture of grasses contains all the elements, in precisely the right proportion, and when in full supply, cannot be improved upon. When other food must be given it should be of a varied character, in imitation of the grasses. The sheep has a strong craving for variety in food, and should be indulged. It is always a strong recommendation of a food that it is palatable—that the animal eats it with pleasure. This is an element of digestibility. Second, habitual full supply of food increases the power of digestion. The full supply of food gives full exercise to the stomach, and its power is increased by this exercise. The blacksmith's arm grows more muscular by the constant exercise of wielding the sledge-hammer; so the animal full-fed from birth acquires a large increase of digestion, and grows with great rapidity to its full maturity. It is this increase in the power of digestion that enables the animal to come full weight in half the usual time of slow growth. Food enough must be digested to make this growth in this short time; and this is the real improvement in the vital machinery of the improved animal.

Let us examine the effect of small and large digestion on the form of animals. If we note the bodies of the sheep kept upon barren hills, or where food is scanty, we find them long, thin-bodied, sharp-backed, long-necked, long-headed, and long-legged. This is the way nature moulds her forms on a meagre diet and slow digestion. An expert animal anatomist could at once tell the liberality of the diet of the animal by an examination of its skeleton. But if we examine the improved sheep of any breed, we find them compact, round-bodied, broad-backed, short-legged animals, rounded out into lines of grace and beauty by superior alimentation,

This improvement might have been very much hastened by selection in breeding, but still, the basis of the improved forms has been skilful feeding, long continued. This increased power of digestion comes of long habit. An animal that has always had scanty food has a very limited digestion, and it cannot suddenly be much increased. The food must be increased very gradually, and the stomach increases as gradually in its digestive power.

It will thus be seen that skilful feeding is the true basis of improving the flock in form. The effect of poor feeding upon the improved Leicester and Cotswold sheep has often been seen, and the deterioration is much more rapid than the improvement has ever been. The flock-owner must, therefore, always regard it as a great misfortune that this flock should be reduced to a scanty ration, even for a short time. No prudent flock owner can afford to economize on the food of his flock; trying to save on their necessary food is simply reckless waste.

The fecundity of the flock can be increased by using a ram from a more fertile breed. When the Cotswold, Leicester, or South-down ram is used to improve the common sheep, the result is to increase the fertility of the next generation. It is also easy to increase the fecundity by selection in the same flock. Breeding will rapidly increase the percentage of lambs from a flock; and this is an item of great importance in a flock used for breeding early lambs. The percentage of lambs from the Merino is usually estimated at 80 to 80 per cent., while in the mutton breeds it is from 100 to 130 per cent. The difference makes a large difference in the profit. The flock owner should study every item, and diligently make the most of it.—*Live Stock Record.*

CINCHONA.

THE HARVESTING OF CINCHONA BARK.

THE following is an extract from a letter addressed to Messrs. Croysdale and Co., by their London Agents, Messrs. Fran Cois Le Maîr and Rivers Hicks, on the harvesting of cinchona bark:—

When slicing was commenced in India three years ago, it was with some trepidation that we observed the departure from the old, well-tried and extremely remunerative process of taking the bark by stripping, and it was only when we were assured of the following being facts, that we expressed our approval, the correctness of which we shortly after saw reason to doubt, and later to be certain that the new process was a most lamentable failure. We were assured that the quantity of bark to be taken would be at least double that obtained under stripping. That the trees were more healthy under the slicing than under stripping. That the bark renewed more quickly under slicing than under stripping. That the yield of alkaloid, and especially quinine, increased more quickly under slicing than under stripping. These four promises proved, as many growers believe them to be, the case would of course be made out, and no sane man would take bark by stripping when he could have or slice. The first slices were undoubtedly richer in quinine and other Alkaloids than the strips taken off the same trees, but that of course had nothing to do with the system, the bark having been grown under the stripping process, and the extra richness was accounted for by their only having taken the outer and undoubtedly richer portion of bark which has not been sliced. The next question, viz., the greater healthiness of the trees under slicing than stripping, was the point which delayed our expressing our antagonistic feeling, for there was no doubt that the trees were healthier under slicing than under stripping, and the first deduction naturally to be drawn was that, if the trees were healthier, the bark must be better; if it were not so, some other influence must be at work. But further observation, that in spite of this phenomenon, bark from trees sliced was each time worse than the last, and that the rate of deterioration was an ever-increasing one, made us feel sure that the argument must be a false one, and in effect, when remembering that the sap of the tree goes up inside the tree, and is there transformed, in Nature's laboratory, into leaves, and comes down outside, down the bark, and is deposited for the most part in the bark, in the shape of alkaloids—when one considers this, all is immediately plain, and actual every-day experience of those whose life is to handle and value bark, triumphs over all the theories. In slicing, you cut through the storehouse of the alkaloid, and leave the contents of the bark on the tree, subject to leakage and to chemical changes, by being exposed to influences they were never intended to be subject to. So far for theory, which as business men we do not believe in. Our theory is made up from our experience. We do not make a theory first, so that even could this theory which we have compiled from observation of effects be overturned by any argument which seems to us very difficult, there would still remain the facts observed to be disposed of, and these are the things that convince us of the suicidal effects of slicing. We have never seen in any case coming through our hands, and where therefore, we had means of verifying the whole matter, we have never seen second slices from identical trees exceed in richness the first slices from those trees. We have observed in very many, too many, cases, a bark arriving the first year in fine, bright, thick, rich slices, commanding the top value, arrive the next year in dull, sickly, dead, thin slices of very uncertain value, and of use to only a limited number of buyers. We have known cases of a crop of bark taken by slicing decline in two years, by about 40 per cent in weight and about 30 per cent of the value,—that is, instead of every 100 lbs. of 2s. bark, only 60 lbs. of 2s. bark, making every allowance for the drop in the market. What the difference after three years' slicing is, we do not know, but we are afraid it would be something deplorable, and it seems to us that

about four years of slicing might reduce a 5 per cent bark to valueless one. Our experience of comparison between the effects of the two processes being chiefly confined to figures, and as to bark from mature trees, you have to face a further consideration, that is, that your figures, relating to young trees, which in the usual course would be fast improving in alkaloid, are likely to be confused by taking any increase in alkaloid, caused by slicing, as an effect of the system; instead of, as we are inclined to think, in spite of the system; so that we should argue that, if a tree, when you get an increase, that increase would be less than it should be by the amount of damage in leakage and chemical changes of constitution of alkaloids, resulting from removing the protecting outer layer of the bark. Under the process of stripping, in alternate layers, on the other hand, you remove the whole quantity containing the alkaloids and the only places where damage can occur is at the edges of the alternate layers left on the tree, and great care is of course necessary in binding the tree up. The advantage of stripping is the damage done to the cambium, and this from two causes. First, scabies, caused by the stripping the cambium with their knives in removing the bark, instead of gently raising it when ready to rise. And the second cause, that of the first, or is closely connected with it, taking strips of bark, on which the bark has not renewed to a sufficient thickness, to allow of its being taken without injury to the cambium. The second cause could easily be remedied by some skilled person going round and making with a patch of paint, or some other easily distinguishable sign, which trees were to be taken. With proper care, trees will go on yielding fine bark for many years, but under slicing, a fine estate may be ruined, at least when mature, in four years. The damage done by slicing is much greater, and sooner perceptible, with crown than with red barks. We advise drying barks at as low a temperature as possible as any higher temperature than 60 is sure to act prejudicially upon the bark. Drying bark at a high temperature affects absolutely the character and constitution of the alkaloids, rendering the separation of the quinine a matter of great difficulty, in fact fatal, to the bark.—*Madras Mail.*

FORESTRY.

A FOREST SCHOOL FOR ENGLAND.

ON Thursday, the 2nd of August, Sir John Lubbock found the opportunity he has for some time been seeking of calling attention, in the House of Commons, to the important question of establishing a forest school in England. He did so when the House went into Committee of Supply and the vote of £23,232 for the office of woods and forests came on for discussion. Sir John asked the Government to consider during the autumn the question of forest education in this country; and whether the natural forests might not be utilised for this purpose. He said:—

So much, indeed, had forestry been neglected, that in Scotland the words suggested deer, but no trees; while the idea of foresters in England was associated with the members of an excellent provident institution. Of course, the Crown forests formed but a small part of the subject. There were altogether, in round numbers, 2,500,000 acres of woods and plantations in this country, so that the subject was one of vast importance. Moreover, it was calculated that in Scotland and Wales there were 8,000,000 or 9,000,000 acres at present almost valueless, and which, if judiciously planted, would give large results. In the science of forestry we were, he feared, far behind most foreign countries, especially France and Germany; and he was very anxious that our landed proprietors should benefit by the experience which other nations had acquired. But let him ask where was a country gentleman who owned woodlands to obtain information as to their management or to procure trained assistants? We had no forest school in this country; we had no class of persons specially trained and instructed in the formation and management of woods. It was, he feared, still true that, as the House of Commons Committee of 1854 reported, timber is "everywhere worse managed than any other species of property." Unless something were done this state of things would continue. On the other hand, the highest authorities had expressed a very strong opinion that we might make our woodlands much more profitable; they showed one step which was a necessary preliminary. The highest English authorities were strongly in favour of the establishment of a forest school, and had forcibly pointed out the loss which our present system of management, or rather mismanagement, entailed on landowners. Mr. Brown, in his standard work on forests, observed that "if our forests had been judiciously managed we should not find so great a part of the woodlands of Great Britain in the unprofitable state in which they are." We were the only important nation in Europe, he argued, Sir John Lubbock, without a forest school, and yet we included our colonies, our forests, were the largest and most valuable in the world. It appeared to be a very strong argument in favour of the establishment of a forest school in this country that at present the young men who were going out to manage our Indian forests had to be sent for instructions to the great French Forest School at Nancy. No doubt, that was a most excellent institution, and we were indebted to the French Government for the courtesy with which they had received our English students; but the system of education given there naturally contained some branches, for instance, the study of French law, that were not adapted to English students, while there were many other considerations, such as climate, which rendered a Continental school less suitable for English requirements. He might add, he said, "that no young Englishmen, as a matter of fact, went there excepting

those interested in such service. For our colonies, again, the establishment of a forest school here would be of very great importance. The best management of their woods would add considerably to the revenue. French foresters had recently been sent to the Cape of Good Hope and Cyprus, it having been found impossible to find any countrymen of our own with the necessary knowledge. It might, however, be asked why the establishment of such a forest school, if it were so urgently needed, should not be left to private enterprise. The reason was clear. A properly equipped forest school must have attached to it a large extent of forest in various stages, and having a variety of climates and soils. This it was obvious, no private institution could supply. He did not, however, say that this would necessarily involve the establishment of a Government school. He understood that the Government contemplated an arrangement with the Cooper's Hill College, but he trusted that before instituting a Government school they would inquire whether such colleges as Christchurch could be made available for the purpose, and possibly some arrangements might be devised by which, under careful regulations, the professor and students attached might periodically visit our national forests. He might mention in illustration, that lately the Cape of Good Hope Government determined to appoint a Forest Commissioner, with an income of £200 a year. They could not, however, find any qualified Englishmen, and were obliged to appoint a French gentleman, even though he could not speak English. The Society of Arts had memorialised her Majesty's Government on the subject, and the presence in this country of Dr. Brandis and Colonel Pearson rendered the moment one of which it was desirable to take advantage. He hoped, therefore, her Majesty's Government would not think him unreasonable if he asked them to consider this important question. Mr. Courtney, the Secretary of the Treasury, whilst acknowledging the value of the suggestions put forward by Sir John Lubbock, said that the Treasury had not seen their way to do anything in the matter, but promised that the subject should not be lost sight of. This is not very much comfort for those who think that the question ought by this time to have passed the stage of 'consideration,' but it is better than none at all, and Sir John Lubbock, who will, we trust, persevere with his excellent movement, deserves the thanks of the public for what he has so far done in the matter. We shall be glad if he will favour us, in an early issue, with his views on the subject, and we can promise him more space for their discussion than that afforded him by the *Times*—*Forestry*.

THE GARDEN.

CULTIVATION OF THE BEAN.

(*Faba vulgaris*, Monach.)

THIS vegetable is an annual, and one of the oldest cultivated plants we possess. Some uncertainty exists as to its native habitat; however, it is generally supposed to be a native of Persia. There are two distinct classes cultivated in gardens, viz., the long pod and broad Windsor. The pods of the former are from 5 to 6 inches long, and contain from four to six medium sized beans. Those of the latter are from 3 to 6 inches long and much broader than the long pod, and generally contain three flat large-sized beans. There are numerous varieties detailed in European nurserymen's catalogues, however all are referable to either of these two classes. The long podded varieties are the most prolific, and succeed best in this country. They acclimatise without any perceptible deterioration in quality, and should therefore be always grown in preference to the broad Windsor sorts.

In the plains, beans come in use about the middle or end of February, and continue in season until the end of April. They should be sown in succession from the middle of September to the end of October. Two sowings are sufficient for ordinary requirements, but when it is desired to have them in season for as long a period as possible, three sowings should be made at intervals of a fortnight between. They succeed best in a deep, rich, and somewhat heavy loam. Where the soil is light and sandy, heavy manuring must be resorted to in order to meet with success. I find the following to be a good and economical mode of preparing the ground. Dig trenches 1 foot deep and 18 inches wide, at distances of 3 feet apart for long podded, and 2½ feet for broad Windsor sorts. Half fill the trenches with old rich manure, and dig or fork it into the subsoil at the bottom of the trench. Then fill up the trenches with the surface soil and also give it a liberal supply of manure. The trenches will now form low ridges owing to the manure and looseness of the soil. They should next be pressed with the feet, and if the soil is still above the surrounding level, part of it should be drawn to each side, leaving a space 18 inches wide down the whole length of the rows. The soil draws away may be left along both edges of the latter for the purpose of facilitating the retention of water when irrigating. The seeds should be inserted 2 inches below the surface in double or single lines in each row at 6 inches apart, and the same distance between the lines when two are sown. The double line is preferable to the single one for the following reasons. If the seeds are imported many of them fail to come up, and the resulting vacant spaces, besides being a waste of ground, give the plot an untidy appearance. In a double row, vacant spaces, as a rule, are not so numerous, besides the plants are much benefited by the support and protection they afford each other during storms.

The germinative power of the seeds is much increased by being soaked in warm water for six or eight hours before sowing. Care, however, must be taken that they are not again dried up by

being inserted in hot and dry ground. When the latter is in the state mentioned, water should be given immediately after sowing, and the ground kept damp by subsequent waterings until the seedlings appear above ground. During their progress water should be freely given, the ground kept free of weeds, and the soil frequently stirred between the plants. When the flowers begin to appear, a slight earthing up around the neck of the plants is beneficial. When the stems are well covered with flowers or when about 1½ or 2 feet high, the point of every shoot should be nipped out. If this is not done they will continue to grow and flower without forming any pods. As already mentioned, the long pod acclimatizes readily. When seeds for future use are desired, they should be collected from the pods lowest down on the stems, as these are invariably the largest and best developed. The bean is not subject to disease or to the attacks of insects when cultivated on the plains.

On the Hills—autumn sowings come in use in May, and by successive spring sowings beans can be kept in season until August and September. A small sowing should be made in October or November for the early crop of the following spring. Those for the main crops should be sown in succession from the beginning of March to the end of May, at intervals of about a fortnight between. The mode of cultivation is the same as described for the plains, and need not again be detailed. The plants are sometimes attacked by a species of aphid or green fly. The best remedy is frequent syringings with soap and tobacco water.—W. G.

—*Indian Forestry*.

THE GARDEN ANEMONE.

THE Garden anemone may (*A. hortensis*) be said to comprise early summer and autumn varieties, so long as may they be had in flower by adopting the practice of sowing at different times. The beauty and almost limitless variety which may be obtained from a cheap packet of seed of the garden anemone is astonishing. We know few plants that present the same rich variety of colours which this fine old plant does. From such high-toned colours as brilliant crimson, down to pure white, through every one of the primary colours, in nearly every variety of shade, the transition from one shade to another is perfect and complete. Then the simplicity of their culture renders them most desirable to all who love their garden, yet neither have much time nor money to spend on it. By sowing a packet of seeds at the present time an excellent crop may be reared for next year's display, in the flower garden, and in fact many years' because the roots are perennial, and may be kept for many years without deterioration of vigour, if well cultivated.

The manner in which they are usually done, however, is not the best. They are sown usually too thick, and so thought is given to the necessity of thinning them out, so as to allow of a vigorous development of the small number which may be required for the purpose of keeping the garden gay. If only a small bed is wanted, or a few patches, the seed bed should be thinned out equally the same as if thousands were required, and the trimmings may be utilized by being transplanted while young to any spot that wants lighting up with flowers, such as shrubbery borders or the margins of paths in the vegetable garden.

The anemone likes a rich soil, but the manure used should not be of a crude nature. It should be well rotted, and, if possible, mixed with old turf from rich pasture that has been stacked for some time to rot. In sowing the seeds there is some difficulty, owing to the woolly covering that envelopes each seed, of distributing them evenly. This may be overcome by turning the seeds into a basin, and sprinkling over them some moist sand and mixing the whole and rubbing them together till the seeds separate; the sand will require to be about three times the bulk of the seeds in order to make a complete separation of the seeds. Sown at the present time, the plants will be strong enough to stand the winter, and may be transplanted next spring as soon as they show signs of growing. They usually do better when sown in lines rather than broadcast, and they can be transplanted more easily when so done, because plants may be lifted with less disturbance to their roots. Sowings may also be made in spring and early summer—say in April, June, and July—which will keep up a supply during the whole of the summer.—*North British Agriculturist*.

ON SOME NEW GARDEN PEASE.

THE number of new candidates for public appreciation that turn up annually now-a-days in every department of gardening is so great that it behoves every one who has a garden, and wishes to make the most of it, to examine and criticise every new comer severely before he accepts it as worthy the reputation with which it is sent out. In no department recently, perhaps, has there been more energy displayed than in the vegetable garden, and perhaps no subject thereof has received more attention than the pea. Being one of the most important of summer vegetables, certainly the most popular, no wonder it has received the large amount of attention it has done. According to a report in the *Gardeners' Chronicle* of last Saturday, we find there are no fewer than seven new varieties on trial at Boreaston Park, which bid well take a first place among the existing sorts already in possession of the public. They are—

Duke of Connaught, a main crop summer pea, a strong growing sort, attaining a height of about 5 feet, free bearing, with large, long, well-filled pale green pods. Described as well fitted for

the exhibition table. Awarded a first-class certificate by the Fruit and Vegetable Committee of the Royal Horticultural Society of London.

Progress is a fine sample of the *ne plus ultra* type, with large broad, pods which fill well, vigorous and free bearing.

Magnificent is described as one of the very finest main crop peas in cultivation. It has very large, broad, long, well-filled and singularly handsome pods of a pale green colour, square at the end, which are unrivalled for exhibition purposes. It grows to the height of about $4\frac{1}{2}$ feet. It belongs to the Telephone type, but has none of the puffy appearance which that variety possesses.

Invincible—which also passes under the name of *Home Ruler*—has large, square-topped pods, having nine to ten fine peas in each.

Victor is a dwarf pea of about 3 feet growth. It is a very prolific bearer, with fine, well-filled, square topped pods, which stand well.

Perpetual is of the Veitch's Perfection type. It is a profuse bearer, and perpetual, as the name implies, carrying its crop late into the autumn.

Duchess of Albany is described as fine, but too near in character to the Duke of Connaught to be considered distinct.

The value of these peas, however, must be taken relatively, and with caution, till they are more definitely proven. There never was a time when peas of a superior kind more abounded than the present, and some of the older kinds, such as Veitch's Perfection Champion of England, and many are unsurpassed for their general good qualities. While, therefore, we should be on the outlook for the results of careful work on the part of hybridizers and selectors, we must make up our minds to some measure of disappointment in following up or keeping abreast of the march of progress.—*North British Agriculturist*.

CHIVES VERSUS SILVER-SKINNED ONION FOR PICKLING.

IT is not generally known that chives make a very delicate and valuable pickling onion. The way in which chives are usually grown, viz., allowed to remain in the same spot for many years, is not likely to lead to the development of roots in any degree fit for pickling, because they are too much crowded to admit of anything but the smallest sized bulbs being obtained. If, however, they are planted out in the month of October singly, instead of in clumps unbroken up, very fine roots for the purpose will be the result. They are milder than the silver-skin onion or the common sorts either, and are more crisp as well, eating more like nuts than pickled onions of the usual quality. The ground should be fairly well cultivated for them, digging well, and giving a fair amount of manure. In planting, drills about six inches apart and about 1½ inches deep should be drawn for them. In these drills the roots may be sown thickly, and covered as if they were peas or any other seed.—*North British Agriculturist*.

MINERALOGY.

THE SINGARENI COAL MINES.

DR. KING'S LECTURE AT THE MUSEUM.

DURING my absence in England for the last two years, the opening up of this country by a more extended system of railways has been under the consideration of the Government, particular attention having been devoted to the coal-producing capabilities of the regions adjacent to some of the proposed lines. It was therefore with considerable pleasure that I saw the Singareni coal-field once more receiving that notice which it deserves. Hidden far away in a little-frequented part of the Nizam's dominions, and very small, it is yet the only field certainly known to contain seams of coal of importance within reach of this Presidency.

It may indeed be said at once, at the outset of this lecture, that there are only two areas of coal-bearing rocks in this Presidency. One of these is at Beddahal in the Godavari District; but after being bored the results were so poor that discontinuance of the explorations was reluctantly decided upon; for any further examination could only have been carried on in ground where the placing of sites for bore-holes would have depended very much on what was little better than guess-work as to the probability of their striking any coal even at great depths. The second field is near Bhadrachellum on the British side of the Godavari; its area is unfortunately very limited, and there appear to be only 21,000 tons of coal, of which little more than one-half can be properly worked. There are, however, other areas not far from these which, though small as compared with the coal-fields of the Central Provinces, are of sufficient extent and capability to make them of exceeding interest to Madras. It is true they are in what is at present a very out-of-the-way region, and—as may be seen on the map—they look infinitely small in the vast area of Southern India; still, the opening up of the country will come in time, and the amount of coal in a field is not always proportionate with the extent of that field superficially. The saying, "little and good" may be applied to coal-fields. The demand for coal is now so urgent and far-reaching that very extraordinary efforts must be made to win it; and I hope, with but few data at hand, to show that the resources of Singareni and the other fields to be mentioned are likely to repay such extraordinary efforts. In fact, that it may be possible, for very many years to

come, to lay the coal down at Madras so cheaply that it will compete very favourably with the fuel now obtained from Great Britain or Australia.

At this point, and before going further with the subject, I shall ask those of my hearers who are up in the geology of Indian coal, to bear with me while I explain a few technicalities which may perhaps make the story of Singareni clearer and more interesting to those not so happily prepared. In describing the geology of India, it has been found convenient to call the country lying to the south of the great alluvial flats of the Ganges and Indus, or the Indo-Gangetic plain, Peninsular India; while all the country to the north is considered extra-Peninsular India. The present argument is confined therefore to certain rocks or formations of Peninsular India. A very remarkable and extensive series of sandstones and other rocks, characterized by the fossil remains of plants and hence often called the plant-bearing series, is developed in the central and north-eastern part of this country, and it stretches down towards the Madras Presidency from the Central Provinces, by the Pranhita and Godavari rivers. This great series contains a sub-division of coal-bearing rocks, but these are not of the same age as the coal-bearing rocks or coal measures of Europe. We do not know of, nor do I think there are, any rocks of carboniferous age in Peninsular India. To put it proudly; this wonderful series of plant-bearing sandstones is a speciality of India; it is also met with in South Africa and in Australia, but it is best developed in India, and—shall I say it?—has been best worked out through the sure labors of Mr. W. T. Blanford, Dr. Flettman, and others among my colleagues. It is in fact an Indian rock system, standing on its own lithological, stratigraphical, and paleontological merits, confined within no limits of European or American classification, but demanding a place for itself in the great geological history, and worthy of its classic name, the *Gondwana system*. A very marked member of the system, or rather of the lower part of it, is the *Damuda formation*, containing the Indian coal measures. Such terms, however, as coal-measures and coal-bearing rocks are apt to mislead, if only in the matter of their being a difference of age between such rocks in Great Britain and in India. Hence, when they are spoken of here, it is safer and better to call them *Barakars* and stones or the *Barakar group* or sub-division of the *Damudas*, and thus the term stands not merely for rocks named after the Barakar river, but for a group of rocks in which the coal proper of India is known to occur.

Thus, when a geologist finds himself on lower Gondwanas, he is on the alert for *Damuda strata*; but if he feels—as I did when walking over the Singareni country—his foot drag over the peculiarly rough surface of *Barakar* sandstones; then, no India trapper can beat him at taking up a trail which shall lead in all probability to coal. Although it has just been stated that the Gondwana system requires a place of its own in Geological history, and that its *Damuda* formation is of a different age to the carboniferous formation of Europe, they can be placed approximately alongside the European order of classification thus:—

| European classification. | | Indian classification. | |
|--------------------------|---------------|------------------------|-------|
| Mesozoic. | Jurassic. | Mahadeva | Upper |
| | Triassic. | Rajmahal | |
| | | Panchet | |
| Palæozoic. | | Ranigunj | Lower |
| | | Kamthi | |
| | | Barakar | |
| | Permian | Talchir | |
| | Carboniferous | Coal-measures | |
| | | Mountain Limestone. | |

Concerning the groups of the *Damudas*, it is only necessary to state that the *Kamthi* do not contain coal, and are not known to have any seams worth consideration. The *Barakars* are coal-bearing *par excellence*.

The *Talchir* formation need only be referred to here because it occurs at Singareni associated with the *Damudas*.

I trust it will be perfectly understood that the term coal is here used for the fuel properly so called which every European ought to be able to recognize at once; though, indeed, absence from home and the not having seen or handled it for years, or carelessness about noticing a stone which is as typical of England as anything else, have made some men so blind that they have mistaken the hard and gray black mineral *tourmaline* for coal, the blackness of colour generally being the one main attribute of an otherwise easily recognizable rock. Other substances such as lignite, like that occurring on the Travancore Coast, or the compressed and partially or wholly carbonized vegetable matter of the alluvial deposits of Pondicherry and Cuddalore, however useful they may turn out as fuels hereafter, are not to be thought of as coal.

There is no doubt about the "stuff" (as some people have called it) of Singareni being coal; several tons of it were brought down to Madras in the Duke of Buckingham's time, when it was tried on the Madras railway by Mr. Trevellick, who reported it as coal without a question as to whether it was anything else. The only doubt was as to its being good enough for the work required from coal or other fuel on the Railway, and the Locomotive Superintendent decided that it was so fitted, if it could be landed at the railway at a sufficiently cheap rate.

The coal-fields now under consideration are situated near the south-eastern limits of the area of Lower Gondwana rocks, that is on the lower part of the Godavari valley, or close to it, Singareni being the only one not absolutely within the drainage area of this river. They are Tatpali on the left bank of the British side of the Godavari; Singareni, Sivaramam and Madavarum on the Nizam's side, and Beddahal in the Godavari District. There are others, such as Lingala, Kamarum, Bandala and Kinarauni, but these are not of immediate interest,

If one of the more important of these fields be only opened up, and an easy and cheap route be made for getting the coal carried away, the rest can be utilised in turn. I say this because, as already stated, the fields are small, and in case of any very extraordinary demand, it is as well to know that there are reserves which shall prevent failure of supply, those especially considering the enormous outlay required to win the coal and distribute it over the land. Singareni, though it be of small size, is the most important field on account of its having been best explored, and because its coal is known to be good in quantity and quality. On the other hand, Sivawaram, Madaveram, and Beddadanol are parts of connected areas in which there may be large extensions of Barakar strata. There are fair indications of good seams at Sivawaram; but so far, Beddadanol has failed to show anything better than poor oozy shales. The Singareni field is situated about 17° 38' N. Lat., and 80° 22' E. long., in the eastern part of the Kundlikonda taluq of the Nizam's dominions. It is about 130 miles from Hyderabad, 50 miles from Hanamkonda through which town it is proposed to run the Hyderabad-Chanda railway, 40 miles from the nearest point on the Godavari opposite Bhadrachallam, and between 80 and 88 miles from Bezvada, whence there is canal way to Madras. Kunnamat, the nearest large town, lies about 24 miles to the South. The country is very poorly populated with few small villages in the midst of jungle; but fortunately for railway purposes in the plains and not hidden away among hills as is the case with some of the other fields. It was even difficult to give this field a name; but it is called after a once large village which, though not actually on coal-rocks, is not far from them. There are about 19 square miles occupied by the Damudas, only 8 of which can be considered as Barakars, a considerable portion of them being covered up or overlaid by Kamthis. When I first found this field, all that was evident to me was that it was one of Barakar sandstones. I soon found that they are associated not only with their overlying group the Kamthis, but that the Talchir for a time underlies them. Such an association of the lower Gondwanas was eminently satisfactory as showing that this field was not a mere dying out patch of a single group; and therefore my hopefulness of finding coal was considerable. My search was eventually rewarded by finding a solitary out-crop of coal in a pot-hole in the bed of the main stream, the waters of which happened to be unusually low at the time. Having thus ascertained the existence of coal, I completed the survey of the field, and pointed out where trial borings should be made. The borings were subsequently carried out by Mr. Heenan, the Mining Engineer of the Nizam's Department of Public Works, and I had the good fortune to visit the place once more while he was at work. On this occasion, the bore-holes indicated that there were other seams besides the one I had found; and altogether my friend was in the highest state of excitement over the quality of the coal and its extent. Sober calculation was however brought to bear on the data so obtained: for, there is no getting over the fact that though a cubic yard of coal weighs about a ton, there are only so many cubic yards in a square mile, and Mr. Heenan had as yet hardly bored over a square mile of ground. I now come to a part of the subject of my lecture, the consideration of which is fraught with considerable difficulty. I refer to the ascertaining of the amount of coal likely to be got out of a field like this, and I must confess to a considerable amount of hesitation in taking it up, because the calculation is beset on all sides by such pit-falls as failure in continuity of the seams, doubts as to whether the seams are always the same, and variability not only in the thickness of the seams, but in their composition. Further, in our examination of the lower Gondwana formation as it extends down the Godavari valley from the Central Provinces, a tendency is observable in the Barakars to hold less and less coal as though they were thinning out or dying away to the southward. Hence the chances are that an outlying pocket of the lower Gondwanas such as this little area might only hold fitful and capricious seams. On the other hand, it is possible enough for such a pocket to be a rich one, and I am bound to state that such appears to be the condition of things here.

Be this as it may, Mr. Heenan completed his explorations, and in 1875 he prepared a *resumé* on "Coal in H. H. the Nizam's Dominions," in which, among the accounts of other fields, he gives an extremely encouraging sketch of the capabilities of Singareni. To this *resumé* I am indebted for the data and calculations which I shall now place before you, and which I shall now take the liberty of discussing, seriatim, as closely as possible by the light of my knowledge of the behaviour of the Damuda formation and its groups in the Godavari valley. For convenience of work and other causes, Mr. Heenan examined the field in two parts, a northern one in which the out-crop occurs, and a southern one. He put the bore-holes down in the first portion over an area of one-and-a-half square miles, outside of which there is still a good deal of Barakars; and in the southern part he bored over about one-and-three-quarter square miles, leaving a similar salvage of sandstones all round. In the northern-half of the field there are four seams of coal, the uppermost having an average thickness of six feet, the next two have an average thickness of three feet each, and the bottom one, at 151 feet below the surface, is sometimes 34 feet thick. The bore-holes appear to have each pierced the four seams, so that the calculated area is the same for each. Indeed, Mr. Heenan specialises the bottom seams as having this area; though he does not venture to estimate its average thickness very closely, as it is on an uneven lenticular bed, thinning out rapidly at the edges. In the southern portion, the four seams are still extant, but they vary in thickness and depth. I will now read to you what Mr. Heenan says of the capabilities of the seams.—"The upper or Klug's seam"—as my friend calls it—"extends over an area of one-and-a-half square miles on an average thickness of six feet throughout, and allow-

ing one-third for pillars, etc., there will be (5,500,000) five-and-half million tons of workable coal." This tonnage is calculated as follows:—A cubic yard of coal being equal to a ton weight, 1½ square miles, which will give double the number of cubic yards, or 9,292,500 tons. It is usual in coal-mining to have about one-third of the coal in the form of pillars or blocks for the support of the roof which amount being subtracted from the above tonnage leaves 6,195,208 tons, rather over Mr. Heenan's estimate. There is always an enormous deal of waste in working coal, especially with Indian coal; while there is sure to be a lot of poor shaly stuff which will not come up to the requirements of railway fuel; I would, therefore, subject the amount given above to a further reduction of one third when the result would be 4,130,134, or say 4,000,000 of workable coal. Mr. Heenan next says:—"The second and third seams extend over a like area, on an average thickness of three feet each throughout, and will produce (8,500,000) eight millions and half tons of workable coal." There is some mistake here, the aggregate thickness of the two seams is only 6 feet, and the area is the same as in the upper seam, hence the probable out-turn must be the same or 4,000,000 tons. I will not enter into Mr. Heenan's account of the bottom seam: he clearly had not obtained sufficient data for a fair estimate at the time of publishing his *resumé*. He estimates, however, that there may be 8,500,000 tons, which I very much fear, will be found above the true quantity. Whatever it be, I refrain from making any guess about it. Suffice it to say that the seam is sometimes very thick, and it may give such thickness of good coal, in the area defined by the bore-holes as to keep the total tonnage of the northern part of the field well above eight or nine million tons. In the southern area, the lower seam thins out to 50 feet in some places, but the quality of the coal is said to be variable. The three other seams are slightly reduced along the western edge of the field. They are somewhat larger, and Mr. Heenan calculates, on a corresponding increase in the probable out-turn, which I would, however, reduce to about the same amount as in the northern field. On the whole, the possible out-turn of good coal may be reasonably reckoned as 16 or 17 million tons, for the whole field: which is indeed vastly larger than I ever expected for so small an area. I am bound to be as cautious as possible in a calculation of this kind; but I must at the same time give due credit to Mr. Heenan's stated facts concerning the thicknesses and areas as shown by his boring explorations. All that we feel justified in doing is to weigh his opinions on the quality of the coal in the seams and the likelihood of their being so permanent in their thickness as he seems to think they are; and I think the reduction I have made on his total estimate of 46 million tons will meet the contingencies likely to be encountered.

The quality of the coal is the next point of interest. That which I myself obtained at the outcrop was tolerably light and compact,—not slaky, but charged slightly with patches of powdery charcoal, breaking into big lumps, and having the bright lustre of ordinary coal. After it had been dried in the sun, it soon made a great blazing fire in front of my tent, which was kept up all night by the people as being something new in that country. The next morning all that remained was a heap of powdered ashes and some fragments of harder cinder which were easily knocked into powder. An analysis, made at the survey laboratory in Calcutta, gave the following results:—

| | | | |
|-----------------|-----|-----|------|
| Fixed carbon | ... | ... | 82.4 |
| Volatile matter | ... | ... | 22.6 |
| (Moisture 6.0) | ... | ... | ... |
| Ash | ... | ... | 15.0 |
| Total 100.0 | | | |

This shows a very fair style of Indian coal; the 15 per cent of ash is, however, just within the limit of coal having a ready sale in India, while the proportion of fixed carbon is much higher than that of average Raniganj coal. The moisture is lower than is usual with Godavari coal. Subsequently, the coal underwent more practical tests. A shaft was run down 200 ft. away from the outcrop to 60 ft. which reached the bottom of the uppermost seam. About 300 tons were extracted and sent to Hyderabad, where it was found to work very satisfactorily, both in the stationary engine and at the workshop forges. On the Madras Railway, about three years ago, experiments showed that the coal is very hard, makes little dust, and leaves very little ash in the smoke box; there was no difficulty in making steam with it, but it was found to make a great deal of ashes in the ash-pail, for which, of course, special arrangements can be made. The great point about these experiments is, that the coal was not thrown aside as being of no account; Mr. Trevethick in his report calls it a "good serviceable fuel;" and says, "that if the facilities for carriage are such as will admit of its being delivered to consumers at a reasonable rate, it should be well worth working." The coal of the upper seam has only been practically tested; but, by all accounts, that of the other seams will be found to be of similar quality. Mr. Heenan gives the following analysis of coal from the lower seam, in which the percentage of ash is remarkably low:—

| | | | | |
|-----------------|-----|-----|-----|-------|
| Fixed carbon | ... | ... | ... | 66.00 |
| Volatile matter | ... | ... | ... | 23.00 |
| Ash | ... | ... | ... | 11.00 |

In considering, now, the means of getting this coal to Madras, or indeed the having it transported anywhere, the depth at which it lies, the nature of the locality, and the means of approach are matters of great importance. The lowest seam is only 150 feet from the surface in the northern part of the field, and it never runs beyond 250 feet; so that the pit shaft or shafts will not involve any extraordinary sinking. Then there will be no great demand on pumping apparatus; the locality is a dry one being in a very small drainage basin of about 37 square miles, at the head of one of the minor feeders of the Munier tributary of the Kistna

river. The situation, as I have already said, is favourable owing to its being in the low country, and thus easily accessible from the wide open plains of Kummummet. It is, of course, a jungly region, of secondary forest; but this will be of advantage in supplying timber for the works and railways. So convenient is this field in every way, that I used to dream of it thus:—If the Nizam's Government do ever carry out a system of railway—as was then proposed, between Hyderabad, Chanda, and the Kistna frontier, via Hanimkonda; why should not a zemindar—say a European—at Singareni, import his mining-plant via Coconada and the Godavari, sink his pit, lay down a tramway from the colliery to Kummummet, and supply the railway at Rs. 5 a ton? I really think still that this might be done at a profit.

This brings us easily to the problem how to get the coal out of the place and lay it down at Madras at a fair rate. In the Government enquiry or correspondence of 1879 on the capabilities of the Singareni and Godavari coal, Mr. Trevethick stated that the cost of the Godavari coal should not exceed Rs. 15-4 per ton, stacked in the Royapuram yard, to attain the same result as is got by using patent fuel at Rs. 22-11-9 per ton. I very much fear that since then the price of patent fuel has gone down somewhat; in which case Singareni must yield its fuel at even a lower price than Rs. 15-4.

The first point is as to what the price may be at the pit's mouth. The coal already mentioned, as having been sent down to Madras, cost Rs. 8-8-2 per ton at the mouth of the shaft. Of course the shaft is only a temporary affair, with no appliances in the way of machinery and the coal was got out in the most primitive manner, at a price very considerably above what could be done at proper colliery works. Coal is sold at pit-mouth, in Rantgunj and other places on that side of the country, sometimes for so low a price as Rs. 2-8 or 3 per ton. At Warora in the Central Provinces, coal is sold to the public at Rs. 7-8 per ton, unscreened; screenings or small coal at Rs. 4, the price to Guaranteed or State Railways being lower. The Warora prices cannot be taken as a fair criterion; the colliery itself was an entirely abnormal Government work, an encouragement work, in fact, and it was constructed at very enormous expense; and worst of all the Government still works it. It seems hardly the correct thing for Government to work a colliery; it is a question, indeed, whether Government should force a commodity on consumers who are not ready for it, or whether this commodity should be allowed to wait until it is wanted when private enterprise will most assuredly get it at a far cheaper rate. It is also a question whether opening up a coal country by roads or railways is not a more legitimate province of Government than colliery work. The intention was admirable; Warora is a splendid work; but it cannot be expected to pay a profit on its cost; it ought to be given over—even at a loss—to people who will work it at a profit. Then, the price of its coal will arrange itself. I think myself that considering the working of Singareni will be comparatively easy, the coal ought to be sold at a good profit at the pit-mouth for Rs. 5 a ton, or, let it be Rs. 6 as proposed by the Consulting Engineer to Government for Railways, in the correspondence of 1859. This Rs. 6 per ton coal has, however, to be carried to Bezvada by railway or road. From all I can learn, there seems every prospect of a railway; and for this carriage it is tolerably easy to calculate the amount to be added to the prime cost. This line of railway will in all probability connect Bezvada with Hanimkonda, which appears to be the place for a great central junction on the eastern side of the Nizam's Dominions, so that it may as well run close to Singareni instead of there being a special coal line 24 miles long between the field and Kummummet. In this case the line from the coal field to Bezvada will be about 80 miles long. It will be, comparatively speaking, over a very easy country. I have walked pretty well over the whole of it going southwards to Kummummet, and then south-east somewhat in the direction of the old high road to Mudalera. No particular stream comes in the way for 24 miles, when the Waira, a strong tributary of the Munier, is reached. Then, rather more east-south-east, over a broken country with another smaller stream at 11 miles; after which, S.S.E. by the village of Yerrapoliham, and so through the pass between the Kondapili and Kowtowwar hills for 25 miles more to Bezvada. There is no use in trying to shorten the distance between the coal field and the latter town to 72 miles in a direct line, as is put down in the Government correspondence. The line I have indicated is the shortest, and I think the most convenient that can be run, and it will be at least 85 miles long. I prefer it to the more obvious route by Partial and the Kistna river, which would run over a troublesome country in the alluvial flats, while it would be 2 or 3 miles longer.

It is hardly necessary to point out how greatly Hyderabad will benefit by such a line of railway irrespective of its traversing a coal district. This eastern Hyderabad country is the poorest region I have been in in Southern India, as far as population and cultivation are concerned; though it has resources of great value if they could only be brought under the influence of commerce and industry. A railway from the Kistna delta will carry produce, and perhaps people into it, and it will carry out produce which at present lies fallow. The Chandra railway, however useful it may be, has to run a much greater distance over a far wilder and infinitely more difficult country. Chanda wants little that Hyderabad can give; Madras requires much for which she will give a fair price.

To return, however, to the subject of the carriage of coal. This mineral is carried in Bengal and Central India, by rail, at about Rs. 2-5 per ton for 100 miles. The Madras Railway rate is much higher than this, and the Nizam's State Railway carries it for about Rs. 3-2. However, perhaps both railways will carry it at a lower rate when they have to carry it in any quantity. Not to spare things down too finely, let the 3-2 rate be taken, and this will raise the price of coal at Bezvada to Rs. 8-8.

There is then the water carriage for 274 miles by canal. Referring again to the Government correspondence of 1879, it appears

that with proper boats and an organized system of transport the rate should not exceed 2 ples per ton mile, which will make the charge Rs. 2-13-8 per ton for the canal or Rs. 11-5-8 as the prices of the canal at Madras; a further slight charge must be added for carrying and stacking at Royapuram yard, which certainly will not run the price beyond Rs. 11-8 a ton, well within the Rs. 15-4 laid down by Mr. Trevethick. It must not be forgotten that Rs. 6 is the proposed prime cost in this calculation; not Rs. 5 as I would have it.

The present normal annual consumption of coal on the Madras Railway is only somewhere about 12,000 tons, equivalent to 16,000 tons of Singareni coal; hence, if there were only this railway to feed and its fuel reserves held out at their present rate, the Singareni field might be expected to last for over 1,000 years. The fuel reserves are uncertain; the Madras Railway Company may require more coal, the South of India Railway is ready to take a very large amount, the eastern system of Nizam's railways will require fuel; and altogether it is not improbable that this annual demand for coal might run up to 50,000 tons in a very short time. With such a drain, this field might hold out for 350 years; perhaps under certain views quite long enough for us in India! On any view, if a greater demand arise, there are other fields to fall back on.

There is one other consideration regarding the transport of Singareni coal, and that is on the supposition that the Bezvada railway scheme might fall through, or remain in abeyance for years. In this case better roads or a tramway must be devised, and then it will be better for such a route to run as nearly as possible straight to the Godavari, when there would be water-carriage without break of bulk all the way to Madras. The tramway would go 40 miles long to a point opposite Bhadrachellam. It would run through a wild country; but regarding it, I can also say, from personal experience, that there will be no engineering difficulties of any consequence until near the river, when deep alluvial gullies, subject to floods, come in the way. The length of waterway would, however, add considerably to the price of the coal, already burdened with the charges on the coal line of 40 miles; indeed, the price at Madras would be just a fraction over that which I have calculated for the railway route. After all, the great advantage in the proximity of the river to this coal field is that, with an ordinary road in the direction indicated, colliery plant could be imported and laid down on the field at a much less cost than by any other route. The port for landing is Coconada, whence there is canal and river way to the Hyderabad country opposite Bhadrachellam.

I hope I have now shown you that Singareni is the immediate field for opening up; that 17 million tons of coal may be reasonably expected to be got out of it—if not the 46½ million tons of Mr. Heenan's estimate; and that a railway between it and Bezvada will help to land coal in Madras at Rs. 11-8 per ton.

The other fields in the neighbourhood are Sivawaram and Madaveram. They, with the so far unfruitful field of Boddadanol, are batches of Barakars situated on different sides of a large area of Kamthi strata which may be called the Ashwarapett region. This area of Kamthi is about 240 square miles in extent, and it lies alongside the zig-zag portion of the Godavari, between Bhadrachellam and the 'Gorgi' of the river. Thence, it stretches down towards the Ellore and Yarnagudem part of the Godavari District.

Sivawaram and Madaveram are situated at the north-east angle of this area on, or close to, the bank of the river; they both contain seams of coal of greater or lesser importance. Away on the western edge of the area, near Chundragunda and Kidnigiri, there is another patch of Barakars which has not, however, given any signs of coal as yet. The probability is very strong that, between this and Sivawaram, there may be a continuous and thus extensive field of the same rocks underlying the Kamthi. This part of the country is entirely in the Hyderabad territory, and Mr. Heenan made a few bore-holes in the neighbourhood of Sivawaram. He found that there is a seam one foot thick at 240 feet from the surface, a four-foot seam at 272 feet, and a third seam six feet thick at 313 feet. The coal of the second seam is reported as tolerably good. All this shows that the prospects of the Sivawaram country are favorable; the depth is at the same time considerable for Indian coal measures.

The Boddadanol Barakars undoubtedly stretch away under the Ashwarapett country, or into the Hyderabad lands; and perhaps also down under British ground towards Ellore. The depth to which borings would have had to be carried had they been started in Kamthi, and the incertitude with which I should have had to point out sites for such opinions, practically frightened me from advising Government to proceed further in the work of exploration. I am bound to admit this in the face of such vastly bolder ventures as were carried out—fruitlessly as far as striking coal rocks was concerned—in the Nerbudda valley under the direction of the Chief of the Geological Survey. There, however, the question for or against the occurrence of coal at a reasonable depth, in a region advantageously placed for the railway, was practically decided; and it would have been for the best had a similar end been gained in this part of the Godavari District. This may yet be called for; it would be eminently satisfactory for us to have a decent field of our own within perhaps 20 miles of the Canal, somewhere in the neighbourhood of Ellore; and on this last view I can only now say that before leaving this Presidency, I hope to prepare a notice of the conditions of the Damudas in that region in case of more extended boring operations. In the meantime, however, too much attention cannot be devoted to the development of the Nizam's field; and I trust this description of them may lead to increased interest in them, not only with the public and the Government here, but with the Nizam's Government.—*Madras Times.*

COAL IN THE KHASIA HILLS.

NOTE ON THE CRETACEOUS Coal-measures at Borsora in the Khasia Hills, NEAR LAOUR IN SYLHET. By TOM D. LA TOUCHE, B. A., GEOLOGICAL SURVEY OF INDIA.

I HAVE visited and examined a section of the coal-bearing rocks situated at the foot of the Khasia Hills to the north of the district of Laour.

The section examined occurs in a ravine, at the mouth of which stands the Garo village of Borsora, about 5 miles west of the point where the Panatibh or Jadukhata river leaves the hills. At the edge of the plains on either side of this village nummulitic limestone is exposed dipping to south-south-east or towards the plains at an angle of 38°. On proceeding up the ravine along a path on the west side of the stream no sections of rock *in situ* are seen, but the path is covered with blocks of a coarse yellow and brown sandstone. The path rises for about half a mile until the mouth of a small steep ravine on the west is reached, in the sides of which the coal seams are exposed.

At the junction of the two ravines carbonaceous shale is seen in the bed of the stream dipping to south-south-east at an angle of 12°. Upon this rests a seam of good coal 3 feet 10 inches thick extending for about 20 yards along the side of the ravine. This is overlaid by 5 feet of shaly sandstone, upon which rests a second seam of coal 3 feet 4 inches thick. This seam has been disturbed by several small faults or slips, and parts of it have been denuded to some extent before the deposition of the overlying sandstone, so that its thickness is not so constant as that of the lower seam. Proceeding up the ravine about 60 feet of fine yellow sandstones are passed over, and a third seam of coal is met with cropping out on both sides of the ravine. The thickness of this seam could not be determined exactly, as a small landslip has occurred in the rocks above, and has partly covered it, but it is at least 4 feet thick, though not quite free from shaly partings. Above this the ground is covered for 50 or 60 feet with the debris from the slip above mentioned, consisting of fine yellow sandstones and shales with many fragments of coal, and above this, again, at the top of the section, is a fourth seam, of shaly coal, 2 feet thick. In the whole section, therefore, of about 150 feet, there are about 12 feet of good coal, distributed in three seams as shown below, in descending order:—

| | | Fe. | In. |
|---------------------------------|-----|-------|------|
| Shaly coal | ... | about | 2 0 |
| Fine yellow sandstone and shale | ... | " | 60 0 |
| Coal seam, No. 3 | ... | " | 4 0 |
| Fine yellow sandstone | ... | " | 60 0 |
| Coal seam, No. 2 | ... | " | 3 4 |
| Shaly sandstone | ... | " | 5 0 |
| Coal seam, No. 1 | ... | " | 3 10 |

Carbonaceous shale, thickness unknown.
Total 138 2

The coal of seams Nos. 1 and 3 is much disintegrated by exposure, so that it is difficult to get good specimens for analysis, but it appears to be a very good coal, with a bright fracture and black colour, containing numerous specks and nests of a kind of fossil resin. This resinous substance, which is characteristic of the coals of this region occurring in cretaceous rocks, together with the position of the seams below the nummulitic limestone, shows that the coal is of the same age as that of the Garo hills and the small basin at Maobelarkar, and is therefore distinct from the coal of Cherra Poonjee, which occurs above the limestones. The coal of seam No. 2 is more compact and browner in colour, and is traversed in all directions by small joints, it also contains specks of the fossil resin. Samples assayed in the Survey laboratory by Sub-Assistant Hira Lal gave the following satisfactory results:—

| | Seam. | |
|-----------------------|--------|--------|
| | No. 1. | No. 2. |
| Moisture | 5.84 | 3.02 |
| Other volatile matter | 35.16 | 39.58 |
| Fixed Carbon | 50.41 | 50.80 |
| Ash | 8.60 | 6.60 |
| | 100.00 | 100.00 |

No. 1 does not cake; ash pale red.
No. 2 cakes; ash red.

The section examined is very similar in some respects to one described by Captain H. B. Godwin-Austen (*Jour., As. Soc. Bengal*, Vol. XXXVIII, Pt. II, No. 1, 1869) as occurring on a small tributary of the Umblay near the village of Nongkeral, about 10 miles to the north-west of Borsora; but to determine whether the coal-measures are continuous between these points would require a more detailed examination of the district than I was able to make. The only means of getting sections in such a country is to follow-up the hill streams in which fragments of coal are found to the outcrop of the seam, and at this season (June) these streams are liable to sudden floods and become quite impassable. If it should be found that the coal does extend between these points, its amount must be very large.

The outcrop near Borsora is very favourably situated for being worked. It is not more than half-a-mile within the hills and at a low elevation above the plain. The coal rises from the outcrops so that mines or quarries could be easily drained. The foot of the hills is only 1 mile from the Patlai river, a branch of the Jadukhata, and during the rains boats can come up to within a few hundred yards of the hills.

Even now great numbers go close to the spot during the rains to carry away limestone from the numerous quarries between Borsora and Lakma.

TEA.

THROUGH THE TEA DISTRICTS OF NORTH INDIA.

(By a Ceylon Planter.)

NOWONG, ASSAM.

THE labour for working tea estates in Assam is procured from two sources—the local villages and the cool districts of Bengal. The former labourers are known as Cacharris, a term which is applied to all local labour. They are generally engaged for short terms only, and receive Rs. 5 and Rs. 6 a month, subject to deductions for non-attendance. This source of labour is a very uncertain one, and the class of men are very untrustworthy. On the occurrence of sickness in the lines, they frequently decamp in a body, to the serious loss and inconvenience of their employers, and any row between one of them and the manager will probably lead to the loss of the whole force. They are, in fact, a most independent race, and it requires great tact to manage them properly.

The Bengal labourer is generally imported under three years' agreements, on the expiry of which term, it is the custom to offer a bonus as an inducement to them to re-engage for a term of years. This labour-supply is the only dependable one in most localities, but the difficulties in the way of procuring it are considerable. It is the usual custom to send native recruiters to the villages, but the restrictions placed by Government on the departure of emigrants, though well-meant, make the difficulties and expense of recruiting very great. In some cases European assistants are sent down to supply the gardens with labour, and the work they have to do is of a most unpleasant nature. The bribery of native officials from the lowest to the highest is a necessary preliminary apparently to securing labour. All proposed immigrants are examined by Government officials regarding their willingness to go, and their fitness for the journey; this, admirable though it no doubt is in theory, and necessary though it may be, adds greatly to the expense and difficulties of recruiting. It is also very generally stated that the local European Government officials do not look on the departure of their ryots, who contribute to the local revenue, and on whom the prosperity of the district depends, with a favourable eye; and it appears that very little help and guidance can be obtained from them. With the police and other native officials, whose power in the case of native recruiters is absolute, bribery is the only possible road to success.

I met one planter in Assam who had been engaged in recruiting labour personally, and who had been treated in the most shameful way in consequence. It appears that he visited the labour districts, and through his native subordinates succeeded in collecting and forwarding the required labour; in doing this it is to be presumed that he hurt the susceptibilities of some native official: for a short time after he arrived at the estate a warrant for his arrest, signed by a European magistrate at the place at which he had been staying, and granted at the instance of a native headman, arrived at the estate, and he was taken back all the way to Bengal. The charge was one of having wrongfully induced a certain labourer, a woman, whose name was mentioned, to leave the district against her will. A lawyer from Calcutta was engaged to defend Mr. B—, and witnesses taken from the Assam garden to Bengal. The case was then proved to be an utterly false and frivolous one, without the smallest foundation, and it was shown that the magistrate had granted a warrant of arrest for a European planter at many hundreds of miles distance, on the mere statement of a petty native headman, unsupported by any trustworthy evidence. The expenses of the case amounted to Rs. 3,000, which the estate had to pay, and no redress was obtained beyond a severe reprimand to the official in question from Government. This case greatly excited public

attention at the time, and is evidence of the unfriendly spirit which is said to be shown by the local official mind to the recruiting of labour.

The cost of importing Bengali labour, greatly increased as it is by the local expenses, is a very serious item in the estimate for tea planting and cultivation. The amount per head varies in different localities, but ranges between Rs. 50 and Rs. 100, in most cases closely approaching the latter figure, and the whole of it unrecoverable. Even at this cost, however, it is impossible, in most cases, for gardens to keep themselves fully supplied with labour, short-handedness being a frequent cause of loss of crop and neglect of proper cultivation. On the expiry of the term for which the labourer has engaged, generally three years, it is the custom to give a "bonus" of Rs. 20 or so to retain his services for a further period. This system has at times led to much ill-feeling and loss, the crimping of time-expired labourers having once been common. A proper understanding on the subject has now been come to in most parts, and crimping, or "inslaving" as it is termed in India, is comparatively rare.

The outbreak of an epidemic, on an abnormally unhealthy season, leading to a large percentage of deaths amongst the coolies means a very serious direct pecuniary loss to the garden beyond what arises from neglected cultivation. All these points, the unreliable character of local labour, the difficulty and expense of importing Bengalis, and the serious loss that an epidemic causes to a garden, make the labour supply, though apparently cheaper, in really dearer and less satisfactory than that of Ceylon.

We are constantly complaining in Ceylon about the forms which we are required to keep in connection with the medical care of coolies; having seen what the Indian Government require of Assam planters in this respect, I cannot but think that we are comparatively easily treated.

I have before me at the present moment a copy of the various forms which have to be kept on the estates, and duplicates of which have to be forwarded to Government. They are nineteen in number!! A separate register of imported, local, and free labourers. A register of deaths of contract labourers, adult free labourers, children under 16, adults living in the lines whether on contract or not, and so on, all separate and distinct. Then registers of sick, of vaccination, and of desertion: a daily attendance roll. The monthly return of births and deaths has 60 columns, and there are also half-yearly returns. In fact, returns of labourers are in their infancy in Ceylon. To appreciate the high pitch of development to which red-tape can be brought, Assam must be visited.

Every garden has to keep a native doctor of some kind to attend to the coolies, and groups of gardens in small districts support a European medical man among them: in fact, the cost of medical attendance on coolies is decidedly heavier in Assam than in Ceylon.

One of the chief grievances which planters have against the present labour laws, and the method in which they are enforced, is the great amount of Government interference in all matters between master and labourer. It is the duty of the Commissioner to visit all the gardens in his district, muster the coolies, and make enquiries as to whether they have been paid to date, what their pay is, what tasks they have to perform, what amount of sickness there has been amongst them: in fact, to hear and enquire into any complaints they may have to make.

Of course, when the Commissioner is a sensible man he does his work in such a way as to discourage frivolous complaints on the part of coolies, but the immense power with which he is invested might cause incalculable harm in the hands of an incompetent crotchety man. Amongst other things, the Commissioner has the power to cancel all coolie agreements, and stop cultivation in a garden under certain circumstances, one of which is a death-rate over seven per cent (epidemics apart), another the coolies' pay being in arrears. When I mentioned that in Ceylon it was usual to have several months' pay in hand, and that the coolies preferred getting two or three months' pay at one time, whilst in some cases financial causes have left them unpaid for a year and over, the statement was received almost with incredulity, and I was told that in Assam such a thing was impossible. The system of paying coolies, and of keeping their accounts, is quite different to ours, and very much simpler in the case of local labour. The strik's name is alone entered in the accounts, and against it the total number of coolies who have worked during the month at Rs. 3, Rs. 4, or Rs. 5, as the case may be, and the total sum so arrived at is paid into his hand for distribution. Strange to say, the coolies prefer this system to any other, and attempts to deal with them direct have failed. Imported labourers are differently treated, and more according to the Ceylon system.

Extra plucking is always paid for in cash on the spot, at a very fair rate, generally one pie ($\frac{1}{4}$ anna) per lb. of leaf, the task being ordinary 16 lb. for men and 14 lb. for women; some of the latter of course making considerable sums during the season in this way. The task is in fact very much the same that is usually got in Ceylon, though, of course, it is always varied in accordance with the size and abundance of the flush. The field cultivation is generally carried on by the local labourers, it being a style of work to which they are accustomed, and requiring less skill and practice than plucking and manufacture, which works are mostly

performed by the more permanent imported labourers. The hoeing of land is done entirely by task-work, and good coolies will frequently earn double and in some cases almost treble pay in a day. Whilst on this subject I cannot refrain from remarking on the great improvement our decimal system is on the anna and pie system in value in India. With our somewhat elaborate check-roll, the latter system would be most inconvenient. It can scarcely be denied that the close supervision exercised by Government over the imported labourers and their treatment has had a beneficial effect. It is said that at one time the mortality used to be very great, in spite of the large pecuniary interest planters had in the lives and health of their coolies: this was due chiefly no doubt to the unhealthy state of the country there, but there can be no doubt that the precautions and care exercised by Government have done good.

Another great difficulty in Assam is transport. At present goods are carried by cart or boat to the Brahmaputra, and thence transported to Calcutta in flats attached to the steamers. The rates charged by the steamer companies are very high, and make the transport of tea from the gardens to the shipping port from two to four times as much as the average rate in Ceylon. The heaviest charges, however, are on goods taken up to the district against stream; and consequently the cost of lead, nails, boxes, and machinery, &c., is enormously increased. As an example I was told of some roofing iron for a factory which cost £50 at home, and the freight on which from Calcutta to Teshore amounted to about Rs. 750.

In transport, therefore, as well as in labour, Ceylon has great advantages over Assam at present. At Debrooghur a railway is being made; is partially completed in fact, up through the tea districts, to where a very fine seam of coal is being worked, and there is a talk of this railway being continued in the direction of Calcutta; but the difficulties, rivers principally, seem very great.

The expense and delay of a journey up the river have been already mentioned: a daily service of very fast little steamers is now being started; they carry mails and passengers only, and do the journey from Dhubri to Debrooghur in a comparatively short time.

T. C. OWEN.

—Ceylon Observer.]

THE CHEMISTRY OF PACKING.

MR. G. H. WIGNER, F.C.S., F.I.C. (President of the Society of Public Analysts), recently read a paper before the London section of the Society of Chemical Industry, in which he pointed out the importance of proper packing in the case of various substances imported and exported.

Amongst the substances requiring the utmost care in packing he specially mentioned tea, and his remarks on this subject will be read with interest by growers in India and Ceylon.

"Tea," he said, "is remarkably prone to 'acquire' any external odour from the air in which it is placed. It is, of course, well known that tea is always packed in cases which are lined with lead. In the case of China teas the lead is tolerably pure, cast into sheets by pouring the melted metal on to one stone and dropping another stone on the top of it. This primitive method produces a sheet of somewhat singular uniformity in thickness, weighing about 2 lbs. to 3 lbs. to the square foot. Indian teas are packed almost exclusively in lead, which is sent out from this country. It is not pure. It contains an admixture in most cases of tin, and sometimes a small proportion of antimony. These are added to enable the lead to be rolled much thinner, and the weight of it is not more than $\frac{1}{2}$ lb. to the square foot. Before any injury can occur to the tea itself, this lead must either be destroyed or perforated, or, at any rate, it must not be in an air-tight condition. It is obvious that, except in cases of neglect, all such goods would be packed in wood which was at any rate fairly well-seasoned. Until recently only, one kind of wood has been used for packing tea. This is a species known as 'toon' wood, and every one who has ever seen a tea-chest made of it must be familiar with its general characteristics. It is easily worked, does not require to be stacked long to season, is free from smell, and not very liable to absorb water. The cases of injury with this wood have been of only occasional occurrence, and appear to have been determined much more by accidental circumstances than by even an occasional failure in the character of the wood itself. But of late years the supply of 'toon' wood has run short; the Chinese have had resort to other woods, and in Assam woods are being used at random."

The rest of Mr. Wigner's paper was devoted to details of injury to teas, resulting, in his opinion, from the wood of the cases absorbing moisture and causing the lead envelope to be attacked, white-lead being often found in larger or smaller proportion on the wood next to the lead.

TOBACCO.

TOBACCO CULTURE IN VIRGINIA.

(BY C. F. BERNLEY, AMELIA CO., VA.)

THE "Old Virginia Leaf" has probably seen its best days. What ever were the means by which the staple attained its great reputation, the planters have not troubled themselves to sustain it. Formerly, the facility of raising tobacco through the double advantage of rich soil and cheap labour, with the profit of ready sale, induced all who could to plant as large a surface of the crop as was possible. Complaints, however, as to quality began to be heard sometimes before the war, but were unheeded, and now, while the demand continues steady, the increased cost of producing the weed, and the decline in prices, have borne heavily on the farmers, and their favourite crop is fast losing its place as a paying product.

To secure a crop of tobacco, two things must be secured—a fall plant-bed and a fall planting. The bed is a spot in the woods, with a southern exposure, cleared off to the required number of square yards, which varies from 500 to 2,000. Great care is necessary in the preparation, the first part of which is burning. This is done to kill all grass-roots, and seeds of weeds, that they may not grow with the plants. Parallel rows of poles (skids) are laid, four feet apart, extending the length of the bed; across these is built a good sized ridge of wood, reaching from side to side, then fired along its whole extent. After burning until the coals and ashes have covered the ground underneath, the fuel is pulled over upon a fresh strip of ground, the process being repeated until the bed is burned all over. A powerful breaking-plough is used to tear up the plot, followed by grubbing hoes and rakes kept going until the charged stumpy area is turned into a nice soft bed of uniform fineness. It is necessary to put strong manure on the bed to make good plants. The seed is then sown, mixed with dry ashes, at the rate of a gill to the 100 yards, and put in by a brush, a small tooth-rake, or by stamping. Plenty of brush must be put on the bed to protect the young plants from late frosts. Having manured his land, the farmer makes lists (throwing three furrows in one), and cuts them into hills. The best planting time is from the middle of May to July; after this, the cutworm and heat destroy all replanting. After a rain, the plants are drawn from the bed, and dropped by one person, for two others, who make a hole in the hill, insert the root, and press the earth close. The working of the crop is the same as with corn. When the tobacco is high enough to have ten leaves, after pruning, the bud is taken out, to prevent seeding, and the plant grows broader and heavier, but no taller. With the second week in August comes the fly which fastens its white eggs upon the underside of the leaf, from which the worms hatch by hundreds. Unceasing attention for three or four weeks is imperative, to keep down worms and suckers, or they will destroy the crop. Cutting is begun about the middle of September. The plants are split from the top to within six inches of the root, severed, and turned bottom up to "fall," after which they are collected in piles of about a dozen each, and hung by the splits on sticks riven for the purpose. Some farmers cure tobacco on scaffolds in the field, but the rule is to house and fire at once. When the stems are dry enough to crack, the curing is done, and some damp day is chosen, when the tobacco is "in order," to strike and bulk it. Stripping is done during winter.—*American Agriculturist*.

BRITISH WEST INDIAN TOBACCO.—The price of Havannah cigars has advanced so much of late years as to afford great encouragement to competitors, and there is no valid reason, says the *Planters' Gazette*, so far as we are aware, why Jamaica, Trinidad, and other of our West Indian possessions should not grow just as good tobacco and manufacture equally good cigars as the neighbouring Spanish colony, provided always that the same care and experience is devoted to the enterprise. In Jamaica there are already several tobacco plantations, whose produce, both in the raw and manufactured state, finds a satisfactory market in Europe, and Mr. D. Morris has been energetically urging an extension of this amongst other industries there. During the last few days Trinidad has also entered the field with a first shipment of cigars, the results of the experiment, are, we believe, such as to afford encouragement to the proprietor of the plantation, Mr. Charles Fabian, jun., and to his superintendant, Mr. Henry Anderson.

NEW PRODUCT SEEDS.

CABARA Rubber seeds, Rs. 70 per bushel; Sappan Dyewood seed Rs. 60 per bushel; Celebrated Caracacas Cocoa (quick growing, early, and heavily bearing variety) Rs. 75 per Warden case, with 60 plants, free, per steamer. Cinchona Ledgeriana seed from trees analysed over 8 1/2 P. S. Q., guaranteed, Rs. 130 per lb. Ledger Hybrid seed Rs. 70 per lb. Cardamom Robusta seed Rs. 30 per lb. free per V. P. Parcel Post. All seeds guaranteed fresh, and good. All orders should accompany remittance.

Seeds and Plants of numerous New Products forwarded to all parts of the world on most advantageous terms. Price List post-free on application.

We have already executed a large number of orders from India.

Enriches Hot Joints, Soups, Stews, &c.

YORKSHIRE RELISH

Delicious to Chops, Steaks, Fish, Poultry, &c.

YORKSHIRE RELISH

Blends Admirably with all Gravies.

YORKSHIRE RELISH

Agrees with the Most Delicate Persons.

YORKSHIRE RELISH

Makes Cold Meat a Luxury.

YORKSHIRE RELISH

Possesses a Pleasing Piquancy.

YORKSHIRE RELISH

Every Dish is Improved by its Addition.

YORKSHIRE RELISH

Suitable to the Invalid's cup of Broth.

YORKSHIRE RELISH

Should be on every Sideboard.

YORKSHIRE RELISH

Epicures pronounce it the Best Sauce.

YORKSHIRE RELISH

No better Sauce can be Made.

YORKSHIRE RELISH

A Household Word.

YORKSHIRE RELISH

Known all over the World.

Warranted pure and free from any injurious ingredient.

This Cheap and Excellent Sauce makes the plainest viands palatable, and the daintiest dishes most delicious.

The most cultivated culinary connoisseurs have awarded the palm to the YORKSHIRE RELISH, on the ground that neither its strength nor its piquancy is overpowering, and that its invigorating zest by no means impairs the normal flavour of the dishes to which it is added.

Employed either "au naturel" as a fillip, to chops, steaks, game, or cold meats, or used in combination by a skilful cook in concocting soups, stews, ragouts, curries, or gravies for fish and made dishes.

Sold in bottles, 6d., 1s., and 2s. each.

Prepared by GOODALL, BACKHOUSE & CO., Leeds, England.

Verdala Barracks, Malta, 21st Feb., 1875.

SIR,—Having been for the last four years Canteen President of the 101st Fusiliers, I have signed orders for at least 3,000 bottles of your Yorkshire Relish, and can bear testimony to its being the best and cheapest sauce extant.—Yours truly, W. SWINTON JERVIS, Capt. 101st Fusiliers, P.C.O.

FIRE BRICKS.

RANEENGUNGE FIRE BRICKS as supplied to Government and the various Railways, Iron Works, Coal, Gas, and Steam Navigation Companies. Price—Rs. 9 per 100.

Extract from Official Report of tests made at H. M.'s Mint, Calcutta, by THEODORE W. H. HUGHES, Esq., F.G.S., A.R.S.M., Officiating Deputy Superintendent, Geological Survey, India:—

"The Fire Bricks tested by me were furnished by the Firm of Messrs. BURN & Co. * * * The materials from which they are made are very refractory and capable of resisting high temperature without sensibly fusing. * * * That compared with Stourbridge Fire Bricks are somewhat superior."

The specimens were subjected to a temperature of over 3,000 degs. Fahr., the smelting point of Cast-Iron being 2,788 degs. Fahr.

Apply for the above, and for Raneengunge Salt-glazed Stoneware and Imperishable Drainage Pipes, to

BURN & CO.,

ZULULAND AND CETEWAYO.

"I know what it is," he answered; "this honey is made from euphorbia flowers, which are very poisonous." This explanation made me feel exceedingly uncomfortable; but I elicited from him that there was not much danger, as the 'maass' taken with it would neutralise the effect of the poison. Directly he mentioned poison I dived into the packs, and pulled out a bottle of ENO'S FRUIT SALT, and emptying a quantity into two pannikins, filled them up with water, and several times repeating the dose, in a few hours we were considerably better."—*Zululand and Cetewayo*, (p. 139), by Captain W. R. Ludlow, 1st Batt. R. F. Royal Warwickshire Regiment.

"What on earth shall I take to Zululand?" asked my friend Jim Law one day at Aldershot, when he had just received orders for South Africa, to start at forty-eight hours' notice. I replied, 'If you take my advice—and it's that of an old traveller—you'll not budge without a few bottles of ENO, even if you leave half your kit behind. I never am without these Salts, and, please the pigs, never intend to be.' On his return I inquired, 'Well, how about ENO'S FRUIT SALT?' 'My dear fellow, it was the best advice you ever gave; they saved me many an illness; and when I left Tugela, I sold the remaining bottles for ten times the original price!'—*Lieut.-Col.*

JEOPARDY OF LIFE. THE GREAT DANGER OF DELAY.

You can change the trickling stream, but not the raging torrent.

WHAT EVERYBODY SHOULD READ.—How important it is to every individual to have at hand some simple, effective, and palatable remedy, such as ENO'S FRUIT SALT, to check disease at the outset! For this is the time. With very little trouble you can change the course of the trickling mountain stream, but not the rolling river. It will defy all your tiny efforts. I feel I cannot sufficiently impress this important information upon all Householders, or Ship Captains, or Europeans generally, who are visiting or residing in any hot or foreign climate. Whenever a change is contemplated, likely to disturb the condition of health, let ENO'S FRUIT SALT be your companion; for, under any circumstances, its use is beneficial and never can do harm. When you feel out of sorts, yet unable to say why, frequently without any warning you are suddenly seized with lassitude, disinclination for bodily or mental exertion, loss of appetite, sickness, pain in the forehead, dull aching of back and limbs, coldness of the surface, and often shivering, &c., &c.; then your whole body is out of order, the spirit of danger has been kindled, but you do not know where it may end; it is a real necessity to have a simple remedy at hand that will answer the very best end, with a positive assurance of doing good in every case and in no case any harm. The pilot can so steer and direct as to bring the ship into safety, but he cannot quell the raging storm. The common idea when not feeling well is, "I will wait and see, perhaps I shall be better to-morrow;" whereas, had a supply of ENO'S FRUIT SALT been at hand, and use made of it at the onset, all calamitous results might have been avoided. What dashes to the earth so many hopes, breaks so many sweet alliances, blasts so many auspicious enterprises, as untimely death?

ENO'S FRUIT SALT.—"After suffering for nearly two and a half years from severe headache and disordered stomach, and after trying almost everything and spending much money without finding any benefit, I was recommended by a friend to try ENO'S FRUIT SALT, and before I had finished one bottle I found it doing me a great deal of good, and now I am restored to my usual health; and others I know that have tried it have not enjoyed such good health for years.—Yours most truly, ROBT. HUMPHREYS, Post Office, Barrasford."

SUCCESS IN LIFE.—"A new invention is brought before the public, and commands success. A score of abominable imitations are immediately introduced by the unscrupulous who, in copying the original closely enough to deceive the public, and yet not so exactly as to infringe upon legal rights, exercise an ingenuity that, employed in an original channel, could not fail to secure reputation and profit."—*ADAMS.*

CAUTION.—Legal rights are protected in every civilized country. Examine each Bottle, and see the capsule is marked "ENO'S FRUIT SALT." Without it you have been imposed on by worthless imitations. Sold by all Chemists, price 8s. 9d. and 4s. 6d.

DIRECTIONS IN SIXTEEN LANGUAGES HOW TO PREVENT DISEASE.

Prepared only at ENO'S FRUIT SALT WORKS, HATCHAM, LONDON, S.E. by J. C. ENO'S Patent.

| | | | | HAMBURG, Tynemouth | 1882 |
| | | | | | Diploma, |

New York, 1880. Melbourne, 1880. Cincinnati, June, 1880.

OVER 450,000 FEET SOLD DURING 1881,

Including 3,877 feet of main Driving Belts, of widths ranging from 15 in. to 60 in., are working in over 6,000 Mills and Works in Europe and America.

The following Tests (by Kirkaldy, of London) show the relative strength and value, compared with Leather.

| Sample taken from Gandy's belt of leather | | Price per foot |
|---|------------|----------------|
| Best Double Leather 6 in. Belting | 3,578 lbs. | 5s. 7d. |
| Gandy's 6 in. x 8-ply Cotton | 6,811 lbs. | 2s. 6d. |

THE
GANDY BELT.

Any Length or Width
for Main Driving.

It is the best belt ever made for all purposes. Much Cheaper and Stronger than Leather. Thoroughly Waterproof, and not affected by temperature, clings well to the pulleys, runs true, and can be made any length without joints. This Series of Belting (see engraving) was supplied in One Order to Messrs. John Crossley and Sons, Halifax, May 1, 1880, and continues to give entire satisfaction.

THE "GANDY" BELT.

GANDY'S Patent American Cotton Belting can claim a superiority over leather belts in every particular; its cost being about half that of leather, while its strength and gripping power is about double that of the best leather, as shown by repeated tests taken by Kirkaldy, of London. These tests are given above, to which special attention is directed. These "Gandy" belts are made of any width up to 72 inches, and any length up to 340 feet without joint, thus obviating the necessity of having two belts on the same pulley, a system of driving which is never satisfactory, as it is impossible to have belts of exactly the same tension; hence one or the other is always causing a stoppage. These stoppages are avoided by using Gandy's Patent Belts in one width. These Gandy Belts are made of the finest American Cotton Duck, specially prepared at Baltimore for the purpose, and then put together and finished by Gandy's patented special Machinery and process to prevent stretching, and render them impervious to atmospheric influence. Possessed of advantages such as these, the universal adoption of Gandy's Belts can only be a question of time.

A SUBSTANTIAL GUARANTEE GIVEN WITH EVERY MAIN DRIVING BELT.

MAURICE CANDY, Patentee and Manufacturer, 130, Queen Victoria-street, LONDON. WORKS: Liverpool, England: and Baltimore. U.S.A.

THE GREAT REMEDY FOR PRICKLY HEAT, INDIGESTION, HEADACHE, BILIOUSNESS, AND FEVERS:

The testimony of medical gentlemen has been unqualified in praise of

LAMPLOUGH'S PYRETIC SALINE,

An possessing elements most essential for the restoration and maintenance of health with perfect vigour of body and mind.

It is Effervescent and Tasteless; forming a most Invigorating, Vitalising, and Refreshing Beverage.

Gives instant relief in HEADACHE, SEA or BILIOUS SICKNESS, CONSTIPATION, INDIGESTION, LASSITUDE, HEARTBURN, and FEVERISH COLIC; prevents and quickly cures the worst forms of TYPHUS, SCARLET, JUNGLE, and other FEVERS, CHOLERA, MEASLES, and ERUPTIVE or SKIN COMPLAINTS, and various other altered conditions of the blood.

Dr. FROST—"Unfolding germs of immense benefit to mankind."

Dr. MORGAN—"It furnishes the blood with its lost saline constituents."

GOVERNMENT OFFICIALS AND PLANTERS caring for the welfare of their employees should note its value as a specific in these cases.

Dr. J. W. DOWLING—"I used it in the treatment of forty-two cases of Yellow Fever, to state I never lost a single case."

Dr. W. EVANS—"Since its introduction the Fatal West India Fevers are deprived of their most dangerous element."

It is REPRESENTATIVE of the GOVERNOR OF SIERRA LEONE, it is an additional supply of the Pyretic Saline, saline—"It is of great value to bear it in the houses of all Europeans visiting the tropics."

Dr. SPARKS (Government Medical Inspector of Emigrants from the Port of London) "I have great pleasure in bearing my cordial testimony to its efficacy."

RAWUL PINDIR, PUNJAB, INDIA—"We firmly believe that the use of your Pyretic Saline will do more to prevent fever than all the Quinine ever imported can cure."

Dr. TUBLEY—"I found it act as a specific, in my experience and family, in the worst form of Scarlet Fever, no other medicine being required."

Dr. GIBSON (formerly Physician to the London Hospital)—"Its usefulness in the treatment of disease has long been confirmed by medical experience."

To be obtained of any Chemist or Drug Store, in Patent Glass-stoppered Bottles, 2s. 6d., 4s. 6d., 11s., and 21s. each. Please note in connection with the recently observed effects of the use of Citrate and other preparations of Magnesia that LAMPLOUGH'S PYRETIC SALINE is warranted not to contain any substance which would cause calculous or other earthy deposits.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bighah in particular varies so much in the different provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

All correspondence must bear the full name and address of the writer, not necessarily for publication, but as a guarantee of good faith. We shall take no notice of anonymous letters.

CORRESPONDENCE.

TEA BOXES.

TO THE EDITOR.

SIR,—Will you allow me a little space in your columns to give publication to the result of an experiment tried by me on wood used in the manufacture of tea boxes. My attention was first drawn to the subject by an article in the *Indian Agriculturist*, dated 1st of March 1883, from which I learned that some pieces of a tea box which had corroded the lead lining, and destroyed the tea, had been sent to India by Professor Dyer of Kew to be identified. As this is a question of great importance to all interested in tea, I determined to try an experiment with the different kinds of wood used by manufacturers in Silchar, and obtained from each workshop two small boards of each kind, one seasoned and the other green. Between these boards I placed a piece of tea lead, tied them together and put them in an almirah. After two

weeks they were opened and examined, with the result that the green board of the wild mango (*Mangifera Sylvestica*) had corroded the lead, the surface exposed to it presenting exactly the appearance described by Professor Dyer—i.e., it was covered by a white coating of carbonate of lead. When held to the light, it presented the appearance of having been perforated with a pin. The surface in contact with the seasoned wood was untouched. From this, it seems pretty evident that the green mango wood contains chemical properties injurious to tea lead, which are either dissipated or otherwise rendered harmless by the process of seasoning. The other kinds of wood had no effect on the lead.

H. J. YOUNG,

Asst. Conservr. of Forests, Cachar Division.

Silchar, October 4, 1883.

THE REVIEWER REVIEWED.

TO THE EDITOR.

SIR,—On the 17th of August last, I learned for the first time that my "Manual of Agriculture for India," had been reviewed in the columns of the *Civil and Military Gazette*. The Editor in his letter of the 15th of August informed me that—"A long review of your 'Manual of Agriculture' has already appeared in the *Civil and Military Gazette*. So far as I remember, the opinions expressed was generally favourable." (Signed), "STEPHEN WHEELER, Editor." This letter was in reply to mine, asking the Editor, if I sent him a copy of the Manual, would he be so good as to review it, pointing out defects, and suggesting improvements, which would appear in the second edition.

On receiving Mr. Wheeler letter, I wrote for a copy of the *Civil and Military Gazette* containing the review, which did not reach my hands till the 25th of September.

The date of this paper, the 3rd of May 1883, attracted my attention, and for the reasons given beneath.

In February Sir Alfred Lyall caused me to be officially informed that, when I received it, I was to forward for his information a copy of my "Manual of Agriculture," and when doing so, to state the nature of the assistance I required, to produce a Hindi translation of the same.

In the latter part of February, and during all March, and up to the 7th April, nearly every overland mail brought me one or more final proof chapters of the Manual, and on the last date, I received, with the chapters, a cover for binding the completed work. On the 8th April, the unbound proofs were made over to a book binder who delivered the bound volume to me on the evening of the 9th April. On that date this was the only copy of the Manual existing in India. On the 10th April, I despatched the volume by Registered Book Post, to the address of Mr. W. Holmes, Private Secretary to his Honor the Lieutenant-Governor of the North-Western Provinces, and in my letter of the same date, I informed him why the book was sent. Mr. Holmes must have received the volume at Lucknow on the 13th of April, and shortly after, by order, he must have made it over to Mr. Bennett to peruse and pass his opinion thereon. The abusive and hostile review which appeared in the *Civil and Military Gazette* of the 3rd May must have been written some time in April for it to have appeared so early in May, and as no other copy of the work existed in India, between the 13th and 30th of April, it is reasonable for me to draw the conclusion that if Mr. Bennett did not write the review himself, the reviewer was some one who wrote under his instruction, or inspiration. Mr. Wheeler letter, tends to show that he *individually* did not write the review, which contains allusions to certain matters stated in my letter to Mr. Holmes, for the information of Sir Alfred Lyall. Hence it follows that as Mr. Bennett

was entrusted with this information, he is either directly or indirectly connected with the authorship of the review in question.

As it may be part of the official duty of the Director of Agriculture, North-Western Provinces, to review scientific agricultural works, and, when convenient, to abuse the author, I trust no objection will be taken to my reviewing a non-scientific agricultural work, which could neither have been printed and published in English, and subsequently translated into Urdu (Hindoostanee), without Mr. Bennett's previous sanction and approval. Thus though Mr. J. B. Fuller, B.C.S., Assistant to Mr. Bennett, is the reputed author, the latter official is responsible for its publication, at the Government Press, and at the public expense.

To introduce the reader to this official work, * devised for the instruction of the rising generation of agriculturists, it is necessary to make a quotation from the review under notice.

Extract.

"The regeneration of Indian agriculture should be no difficult matter, considering the number of teachers who are ready to come forward and instruct the unenlightened masses. Each, according to his own lights, has adopted a special method for carrying out his object. We have an ultra-scientific *Manual* by Mr. Robertson, of the Madras Saldapet Farms; the absurdities of the *Indian Agriculturist*, the easy and useful *Primer* by Mr. Fuller, of the North-West Provinces, Agricultural Department; and last, but not least, we have a *Manual of Agriculture for India*, by the well-known Lieutenant Pogson."

The London Press, connected with India, having expressed the highest approbation of the condemned *Manual*, and the Lieutenant-Governor of the Punjab having bespoken five hundred copies of its translation into Punjabi, is a rebuff which it is to be hoped will be felt and remembered by the reviewer, who has only to study the *Manual* with care to comprehend the difference between a practical scientific work on agriculture, and a departmental production, which would never have been printed as it stands had the copy been submitted to Doctor King or the distinguished Superintendent of the Saharunpore Botanical Gardens, who would have pointed out that the cotton flower does not contain *pillars* of different sizes, nor *knobs* of different sizes and forms, nor small *boxes* filled with yellow dust, as stated by the author. The extracts given beneath speak for themselves, and show the value of the easy and useful *Primer*.

Extracts from the "Agricultural Primer," of the North-Western Provinces.

"There is a very great difference between a plant and an animal, but perhaps not more than between some animals and others. The difference for instance between an elephant, and the tiny creatures which swim about in dirty water, is almost as great as between an elephant and a tree.

"Although, then, there are great differences between the common sorts of plants and animals, yet it is extremely difficult to make a rule which shall exactly distinguish between them. Both are alike in *being alive*—that is to say, in being born, existing for a limited time, and dying again; both grow by taking in food from the outside, and altering it, till it becomes in substance like their own bodies." (From First Lesson.) Remarks. An animal is born alive, and has a father, and a mother; a carrot or cabbage seedling is not born and has neither father nor mother, as the seed from which it germinates is not alive. No rule is necessary to distinguish between an elephant, and the *peepul* tree on whose branches it feeds. The ass feeds on thistles, the elephant on sugarcane, and its producer the zemindar does the same, yet according to Cawnpore doctrine, "it is extremely difficult to make a rule which shall exactly distinguish between them."

"By means of these magnifying glasses a flea can be made to look as large as a mouse, and its eyes and even teeth be seen as easily as those of a mouse. When plants were looked at in this way, it was seen that they were made up of little bags, just as an orange is, each bag being filled with liquid. If a piece of plantain stem be cut across, and looked at, a great number of tiny little holes will be seen in it. These are the ends of little tubes which run up and down the stem, and which are believed to be merely rows of bags, with their ends knocked out. The green substance of which the plantain stem is composed, is made of little bags, shaped like bricks, and fitted one to another, like a mass of masonry, through which these little tubes run like water pipes."

Remarks.—Can such twaddle, about bags, bricks, holes, water pipes, and tubes, which run up and down the plantain stem be called instruction in agriculture?

"Just as the root answers to the *mouth* of animals, through which nourishment is taken in, so do the leaves answer to the stomach, in which this nourishment is digested."

"It is in the leaves that the green colour peculiar to plants is chiefly noticeable. It is caused by a vast number of little green balls inside the cells of which the leaf is composed."—Third Lesson, pp. 11 and 12.

Remarks.—Let the reader translate the above into Hindoostanee, and then after reading the translation to a servant, ask him to explain what it means?

In Lesson IV., pages 13, 14 and 15, the cotton flower is thus described for the instruction of the zemindar's sons:—

"Under the cup there are the five yellow leaves, which form the bright yellow flower." "Inside these yellow leaves again you will see a kind of small pillar, covered with little yellow knobs, from the top of which protrudes a knob of different shape and very much larger than the others. Pull off the five yellow flower leaves and split up the centre pillar, with your finger nail, you will see that the little yellow knobs all come off together, being fastened to a strip of whitish coloured skin. This white skin forms a tube, and round another thinner pillar inside it, and you will see that the large top knob belongs to this second pillar, and remains in its place, when all the small knobs have been pulled off together, with the skin they are fastened to. The inside pillar leads down to a roundish mass, which is the unripe cotton pod." "The white skin tube is covered with little knobs, each of these little knobs is a small box filled with yellow dust. They burst when the flower opens, and the dust is scattered about. If you open a fresh flower bud, you will see all the little boxes, as they appear before bursting."—Lesson IV, pp. 14, 15.

"Plants like animals grow by feeding, just as an animal is only able to live, and grow by taking in food; so also without food, plants immediately wither and die; animals can only live on vegetables, or animal food, they cannot subsist on minerals such as stone earth, sulphur or iron. But plants live almost entirely on minerals. The food taken by the plant roots is not so important as that taken in by the leaves. Of the different substances of which a plant is composed, the most important exist in the air, in the shape of a gas, or vapour, mixed with another gas."—Lesson VI, pp. 20, 21.

In Lesson XIV, page 69, the student receives instruction on the subject of dealing with the sterilizing salt called *Reh*, in the N.-W. Provinces, and *Kullar*, in the Punjab.

"In the cold weather, before the rains begin, shallow trenches should be dug, or scooped right across the field at about 2 feet apart, these should all slope towards a pit which should be dug in one corner. It is during the heat of April and May that the *Reh* chiefly comes to the surface, and when the rain falls, it will dissolve, and run down the trenches into the pit. After a month, the pit should be closed with earth, and by degrees in this way, the "*Reh*" can be gradually washed off *Usar* land, and the soil be made capable of cultivation. The reason why, unless this be done, *Usar* land can never improve, is that, each year the rain water carries the *Reh* down into the soil with it, and brings it up again, when it evaporates just like the bucket of a well—up and down, up and down."

At page 67, and in Lesson XIV, the young ryot and zemindar receive instruction on the subject of irrigation. He is told that "the water enables the crops to eat up more food substances than can be prepared for them during the year, by the action of the sun, rain and air on the soil, and the plants are therefore like a man who eats up his whole month's allowance of food in fifteen days, and has to starve for the remainder."

Remarks.—Assuming that there is an ample supply of plant food substances in the soil, these are never named by the Author, in any part of his work either from want of knowledge, or studied reticence; it is out of the power of the plant to play the glutton as described. The zemindar floods his land with canal water, which being pure spring and snow water, derived from the Himalayas, dissolves far more plant food (namely, Humic acid, and the phosphates of soda, potash, lime, magnesia and iron) than is needed by the growing crop, and as this solution sinks downwards, by the mere force of gravity, it in time gets beyond the reach of the roots and rootlets of the plants, which suffer not from repletion

* An *Agricultural Primer*, for use in Indian Elementary Schools and Classes. N.-W. Provinces and Oudh Government Press, Allahabad.—Second Lesson, p. 4.

* *Usar*, is Sanscrit for naturally barren land. Such land is hopelessly barren, and has not been sterilized by *reh*, due to canal irrigation.—J. F. F.

but from the food needed being placed beyond their reach. The water of nearly all wells contains more or less lime, and alkaline and saline matters in solution which act upon the iron and phosphate of lime present in the soil, and so form plant-food. Land under well irrigation cannot be flooded, whilst fields under canal irrigation are flooded at each watering.

The *easy and useful Primer* under review extends over 84 pages, 72 of which bristle with the wonders, and blunders, corresponding to the extracts quoted, and as these are no doubt repeated in the *Urdu* translation (priced at five annas per copy) intended for the use of village schools, it is easy to understand Mr. Newfield's opinion "that vernacular education in the North-Western Provinces and Oudh Government Schools was utter rubbish, inasmuch as the vast majority of the pupils never remembered anything that they learned." The pupils on their part, may very justly retort, that if the instruction imparted to them was rubbish, the sooner they forgot it the better, and Mr. Newfield has only to peruse the *Primer*, to be satisfied that it comes under his condemnation, and is not worth remembering.

J. FRED. FOGSON.

TEA CULTIVATION IN CEYLON: IMPORTANCE OF SUPERIOR SEED.

(To the Editor of the Ceylon Observer.)

SIR,—There can be now little doubt that in the course of a generation our infant industry, tea, will have superseded all other productions in a great degree, and have become the principal export from Ceylon, and it behoves us as the introducers or pioneers of its cultivation, to do all that lies in our power to ensure the success and permanency of the new undertaking. Our planters are proving themselves capable of thorough manipulation in the manufacture of the invigorating leaf, and with the climate we possess to help them conjointly with their agricultural attainments (of no mean order), its production in paying quantities may be taken as an established fact.

But there is one point connected with the cultivation of the many varieties of economic plants that have been and are being grown in this island, which has never received the attention it deserves, and on looking closely into the matter, it seems almost incomprehensible why such an important factor in the typical perpetuation of the species under cultivation should have been so neglected. I allude to the utter want of any attempt on our part to maintain the continuance of reproduction of the species under cultivation on scientific grounds, in such a manner as to ensure that the plants for future clearings shall be, if not actually superior to the parent trees, at any rate their equal, and to reduce the possibility of any deterioration in succeeding generations to a minimum. In fact no pains or trouble should be spared in endeavouring to increase the suitability of the future generations of the tea plant for the use they will be put to.

Now, if we turn to the mother-country, we will find that the attention both agriculturists and horticulturists there pay to this subject, at once shows it to be one of vital importance, and it has by degrees come to be almost a science in itself. No farmer or gardener would for a moment think of obtaining whatever seed he might require, in the haphazard way we do, from any parent stock that appears to be of good quality, for he has found by bitter experience that those qualities are transient, and that his only way was to obtain the seed he required by the combination of carefully selected varieties of the same stock. To most, this was a matter of great difficulty; for to be successful, an undivided attention must be paid to the subject, and to meet this difficulty these enormous seed establishments and nursery gardens have sprung up during the past half-century, and that they were requisite has been proved by their success.

It must not be inferred from the foregoing that I am advocating the erection of similar establishments in Ceylon. If tea happened to have been an annual, I believe they would have been found necessary, but what I do feel is required, is that the quality of any seed I might purchase either for myself or my employers should be undoubted, and that there would be no fear of the plants from such seed being inferior to the parent. That a large percentage of the cinchona seed sold in Ceylon during the past few years may be characterized as rubbish, few will gainsay, and a small proportion of tea seed may be classified in the same category. I have been victimized in both quite unwittingly on the part of the seller, and it is for the purpose of endeavouring to commence a movement to

counteract this tendency of plants to produce inferior seed that I now write.

The manner in which this desired result is to be obtained, I must leave in abler hands than mine to determine. All I can do at present is to draw attention to the want, and if this want be generally admitted, there is little doubt that a satisfactory solution to the problem will not be long of coming. In the meantime, I would suggest that those who are making small plantations for seed-bearing purposes, should not confuse the same to one kind of seed; for instance, if indigenous Assam be required, the parent trees should be from seed from different sources (indigenous), and planted out alternately in equal proportions; if hybrid, they should be composed of different hybrids of the best class, with a few indigenous or China plants through them, according to the elevations for which the seed will be required; this in any case cannot but be beneficial.—Yours faithfully,

SWADDY.

The Indian Agriculturist.

CALCUTTA, NOVEMBER 1, 1883.

INDIAN AGRICULTURAL DEPARTMENTS.

AN English contemporary very recently took occasion to make a very long and elaborate official paper on bee-keeping in India, issued by the Government of Madras, the peg on which to hang a series of criticisms, more or less reflecting on the Government of India. We are not at present specially concerned as to how those criticisms may be met and disposed of by the department concerned, but it seems to us that there is considerable room for men of scientific attainments, in say the *Agricultural Departments* of the various presidencies. We do not for a moment wish to underrate the very eminent Geologists, Palaeontologists, Mineralogists, Chemists and Botanists, who are in the service of the Government of India. These eminent men are either absorbed by the Geological Survey or by Government Gardens, maintained for scientific purposes, or otherwise fully occupied, so that little if any of their time is available for work outside the routine of their several duties. We do hold, however, that there is a wide field and a pressing need for trained adepts in the physical sciences being attached to each of the Agricultural Departments of India. We do not say that the Indian Agricultural Departments are distinguished for their knowledge of agriculture either of India or any other country. The method by which appointments are made to these departments renders such a consummation, useless in rare instances, scarcely possible. Apart, however, from the fact that there are few men in the departments who have had a special agricultural training to fit them for the posts they occupy, the usefulness of these departments to the Empire is seriously impaired by the additional fact that, from top to bottom of the departments, imperial and provincial, there is scarcely to be found a man of distinguished scientific attainments. How any Government persuades itself that it is serving the best interests of Indian agriculture, by attempting to carry on an Agricultural Department without the assistance of the most eminent scientific observers it can procure, is a problem totally incomprehensible outside of officialdom. The farmers' co-operative societies of England are able to secure the services, as consulting chemists and botanists, of some of the best known scientific men in England. There is scarcely a State of the American Union, which has not its scientific man, more or less distinguished, attached to its Agricultural Bureau. To say what France, Germany, Italy, and even Australia have done, and are doing, in this direction is to repeat what ought to be well known at all events to those who are supposed to be leaders in agricultural matters in India. Nevertheless, as we have said, the Government Departments of Agriculture are distinguished not for the scientific attainments of their officers, whose reports and notes on agricultural matters ought to bear

with them the highest authority, and be final ; but on the contrary, they are characteristic of the commonplace and in some instances of the questionable. It seems to us the height of legislative folly to establish departments which are supposed to deal with technical and scientific subjects, and then subject the reports of these departments to the criticism of provincial Secretaries, who know little or nothing regarding the topics dealt with. If anything could have been devised better fitted to bring Indian Agricultural Departments into contempt, and secure for their labours the least possible amount of usefulness, we shall be glad to learn what it is. As it stands, the department is officered by clever civilians and military men, who, as a rule, though not always, are able to write essays quite as deftly as the other clever civilians, who in the official capacity of Secretaries to Chief Commissioners and Governors, and Lieutenant-Governors revise their work. We venture to think that until men, with a training more or less purely scientific, officer, in large numbers, the Agricultural Departments of India, the departments will scarcely justify their existence. We do not mean men who have distinguished themselves at examinations by exhibitions of brute-like memory of facts and text books ; but men who have shown practically that their powers of observation and experiments have been trained and perfected in the field and laboratory. Men of this sort are not to be had every day ; whereas men who can cover acres of foolscap at examinations, and pour out the contents of text-books and lectures, can be had common enough ; and the bulk of mankind accept the latter as the pure gold, instead of the hollow tinsel dummies that some of them are. Men of the sort we have indicated as suitable for the work of the Indian Agricultural Department cost money, and money is a consideration of considerable moment. Could there not be fewer of the " writing beggars," and an increase in working, scientific men, not mere book crammers ?

THE EXTERNAL TRADE OF BENGAL.

THE " Report on the External Trade of Bengal with Nepal, Sikkim, and Bhootan for the year 1882-83 " has a most imposing appearance, being too tall and too broad for most bookshelves, and bound in the most stiff and uncompromising fashion. It does not, however, contain as much matter as an ordinary newspaper, consisting of thirteen pages only of large type, and it is just possible that the information it contains might have been put into the annual trade report, without much loss except that of diminishing the returns of the Bengal Secretariat Press. The subject is one of interest, however, and we should welcome a separate volume on it, if the excellence of the composition at all corresponded with the admirable appearance which the book presents, when viewed from the outside. If we may be allowed to make a suggestion, it would be that the official gentlemen who write these reports should be required to sign them. They would then, perhaps, take more pains to convey their information in a readable shape, whereas it seems that books " published by the Government of Bengal," without further specification of the author, are intended rather to show obedience to the order that a book should be written on such and such a subject, than to interest or instruct any one.

While glancing at the figures in the report, we sometimes feel inclined to ask, " Is that all true, or only a story ? " There are thirty-two registering stations along the Himalayan frontier, all at lonely places, and there is a natural suspicion that the registering clerks may prefer fishing in the hill streams or visiting their friends, to counting carts, bullocks, and coolies as they pass by. Considering the love of the Bengalees for statistics however, we might not hazard the expression of the doubt, were it not for the statement that " the Lieutenant-Governor is unable to accept the figures of the two years previous to 1882-83 as being finally correct, as the result of the enquiries made through the Deputy Commissioner of Julpigorie, under the orders of the Government of India, regarding the shell-lac trade registered in those years, showed that the figures of the trade submitted to Government since 1878-1879 were for the most part fabricated by the registering mohurrirs at Buxa and Ambari stations." We agree that figures should not be accepted as " finally

correct," when it has been proved that they are fabricated, and we wonder respectfully at the word " finally " having been used. Is it supposed that a certain correctness should be attributed to all official figures, even when we know them to have been invented by the clerks ? The two mohurrirs were found out in consequence of the unusual interest taken by the Indian Government in the subject of shell-lac ; and the question arises, were the other thirty immaculate ? Had they also a power of imagination, a development of the inventive faculty, a gift for dealing with figures, not only in the way of marshalling and arranging, but of positive creation ? We notice that the Darjeeling Deputy Commissioner is likely to prove, without knowing it, a patron of this form of original literature. When the line that was at first modestly called the Darjeeling Tramway, and now more magnificently the Trans-Himalayan Railway was opened, and a road made in connection with it to the Joylap Pass, it was reasonably expected that the facilities thus afforded to trade would lead to its increase. When none followed, the Bengal Government enquired the cause, and the Deputy Commissioner replied, " I dare say that inattention to orders on behalf of the registering clerks, may have affected the returns in the past, but I am doing my best to rouse them, and have, as reported above, only recently thoroughly inspected the stations. Both clerks have been warned and one temporarily suspended, and I hope that no indolence on their part will hinder the improvement which I believe to have really set in, in the Thibetan trade." We hope that the two clerks are men of discernment and sterling honesty. If they are ingenious, they will argue that Government having made a road and encouraged a railway, naturally expects an increase in the traffic : failing to show this, we have been " thoroughly inspected by " a Deputy Commissioner, in itself a fearful punishment, and we have been " roused," warned, and one of us " temporarily suspended." This we now see is what happens to registration clerks who do not show an increase of traffic, when Government requires it, to justify its new road towards Thibet. For the future, we had better send in returns indicating an increase every month, and then our friends at home will no longer hear of our being inspected, roused, and temporarily suspended, over these desolate Himalayan heights. Perhaps if we can ascertain the views which the Lieutenant-Governor is said to have expressed to Lord Ripon, and support them by the right supply of figures, we may get away from the hills altogether, and be put on the more pleasant and profitable work of registering traffic where the Nuddoa tolls are collected. We give this as a possible line of argument of the ingenious clerks who invented the figures as to the trade in shell-lac, and without the slightest insinuation against their comrades at Darjeeling, who, we sincerely hope, are much above entertaining such sentiments.

As to the figures produced, no one can object that they are not sufficiently minute, giving in abundance the details desired by merchants. The total value of horses which crossed the Nepal frontier for British territory was Rs. 1,200 ; of canes and rattans, one rupee ; of precious stones, during the last year, when any came, Rs. 700 ; of manufactured leather, Rs. 262. These, we can believe it possible were the property of a solitary horseman, on a nag of the average price now asked for the walers imported to Calcutta, carrying a riding cane, a valuable ring, and with a most exaggerated idea of the worth of his boots, saddle, and bridle, as leather. Among the exports to Nepal, we notice Rs. 25 worth of lime and limestone, Rs. 4 worth of bricks, Rs. 11 worth of coal, Rs. 4 of assafetida, Rs. 36 worth of liquors, Rs. 33 worth of firewood, the total value of the exports under these six heads being Rs. 113. Similarly in the returns of the trade to and from Sikkim and Bhutan, there are a number of items of five rupees and under. Any ordinary traveller crossing the frontier should fill the return with a vast variety of articles as important as those noted. We felt inclined to remark that a great deal of space might have been gained by the judicious grouping of these petty items of trade. But then there may be a difference of opinion as to what constitutes gain of space. To a book-maker anxious to pad an attenuated volume, it is vain to recommend condensation.

The tables appended to the report show that the imports into Bengal from the frontier state of Nepal, were valued at

107 lakhs in 1880-81, and at 82 lakhs in each of the two following years. Our exports to the State have been uniformly valued at 82 to 87 lakhs. The exports to Bhootan have fallen from two lakhs to one, and the imports are represented by nearly the same figures. The exports to Sikkim have increased from something less than one lakh to something more, and the imports from that country have at last reached the figure of two lakhs. The trade with Nepal only is considerable, and our imports seem to be mainly from the country of the plains, the staple being rice. An attempt was made to ascertain the duties levied in Nepal on trade with Bengal, the enquiries not being addressed to the Resident—who is supposed to sleep for eight months of the year at Khatmandoo—but to the Collectors of the districts in our territories. It is the rule with the Bengal Government whenever it wants to learn anything, to ask the Collectors, and they reply to all questions. Sir George Campbell used to keep a stock of such questions as:—What is the average weight of a Patna sheep? What is the consumption of tobacco per head of population in this province? What is the percentage of polygamous Hindoos in your district, to those with one wife? And it was supposed that he would make an interesting book out of the answers given by the Collectors, when he had time to reconcile them. We observe that the Collectors have very readily furnished tabular statements of the duties levied in Nepal, but that they do not in the slightest degree accord. The Collector of Chumparun says, there is an *ad valorem* rate; the Collector of Mozufferpore that the duty is levied on the land irrespective of its value; and his brother of Darjeeling supports him in this, but gives double the rate. This applies to rice, but in no one item can any possible agreement be found. Perhaps the duty may be left to the discretion of local officers, but the Bengal Government seems to incline to the belief that the reports are 'inaccurate,' to put it mildly.

EDITORIAL NOTES.

IN acknowledging the annual report on the production of Cotton in the Central Provinces, the officiating Secretary, Mr. A. H. L. Fraser, says:—"I am also to state that the Chief Commissioner is unable to accept the estimate of 100lbs. per acre even for the Wurdha district. In Berar, where it has been possible to ascertain the amount of the out-turn with almost mathematical accuracy, the out-turn is much less; and Mr. Jones does not think that in a province in which cotton is so unequally distributed very safe results can be obtained on the method adopted in paragraph G. It seems to the Chief Commissioner probable that the chief source of the error which you notice is to be found in the Wurdha estimate of 30lbs. In this district the acreage under is more than one-third of the total acreage under cotton in the province, so that any error in the estimated out-turn of this district produces an immense error in the estimate of total production. This Wurdha estimate is probably, notwithstanding the badness of the season, as much under the mark as the estimate of 100lbs. would be above it. If we raise Wurdha to 50lbs., and similarly raise some of the other districts in which the out-turn is obviously too low, the facts of the year will be explained. The remark made by you that a wet year is a bad year for cotton is entirely in accord with Mr. Jones's experience."

"The value of the cotton crops according to your returns, which are certainly too low, is put down at over 47 lakhs. It would not perhaps be very unsafe to raise it to nearly 60 lakhs, that is to say, that it equals the whole land revenue of the province. In the Wurdha district the value of this crop far exceeds the land revenue."

"I am to add that in future reports information should be given regarding the presses and mills at work in the province; and statistics showing the exports of the principal exporting stations would also be of some interest."

SUCH an eminent authority as Sir J. B. Lawes is doubtful as to the feeding value of ensilage, and he thinks the loss of nutritive matter in the silo is so large as to make it unprofitable

as an auxiliary to British farming. Mr. Woods, on the other hand, in narrating the results of his experience, dwelt on the value of ensilage as a succulent food for milch cows and ewes, and he illustrated this by giving figures showing a marked improvement in the quantity of milk and the quality of cream yielded by cows fed on the new fodder. The analysis he obtained of the ensilage also showed it to be a succulent, highly nutritious, and easily-digested food. A different result has, however, attended experiments in Canada, conducted by Professor Brown during the past season at the Ontario Agricultural College and Experimental Farm. These showed that ensilaged corn fodder gave 15 per cent less milk, 30 per cent less butter, and a poorer marketable butter in colour than when the cows got Swedish turnips. Although the animals ate the ensilage readily to begin with, they gradually tired of it and fell off in condition, until other food had to be added.

Mr. Woods' testimony as to the merits of ensilage, however, receives strong practical corroboration from the official report of the United States Department of Agriculture. This report embodies the experience of about 100 agriculturists in the United States and Canada, and in reply to a schedule of questions submitted to them they express themselves as having no doubt of the profitableness of ensilage. The condition of the stock eating the fodder was uniformly good, both as regards health and gain in weight. Milch cows are more generally fed with ensilage in America than any other class of stock, and it is in this connection that it is expected to prove of greatest service, the majority of the correspondents stating that there is a decided increase in quantity and improvement in quality of milk and butter from cows fed on ensilage. The quantity of fodder given to each cow in the States varies from 50 to 60lbs. daily, in addition to some dry fodder and grain.

The common practice in America, and we believe it is the one which, under general circumstances, it will be best to adopt, is to place the crops in the silo when their full growth has been reached, and before ripening begins. In the United States most farmers favour fine cutting, a half inch or less, as it packs closer, and is likely to keep better; but if stored whole, and firmly compressed, it has been found to keep very well. The fodder should be kept level during the process of filling the silo, and be well trodden. In nearly all the answers to Commissioner Loring's queries, it is stated that the loss, by decay, on the silo being opened, was very slight, and confined to the top and sides, where there was more or less exposure to air; and generally it had kept perfectly well for several months, and showed no deterioration.

After all, however, the important point is how far this new method of preserving fodder is suited to the peculiar conditions of this country. American experience will not settle that question to the satisfaction of British agriculturists, and, therefore the results of the experiments at present being carried out will be anxiously awaited. Should they confirm the hopes that have been held out—and in the light of what has already transpired, there is as yet no reason to doubt it—a fresh impetus will be given to agriculture, and the farmer, will be fortified in no small degree in contending with the difficulties of a severe winter.

EXPERIMENTS on the temperature of the soil are being carried on at the Houghton Farm, New York. The soil is a gravel with a clayey sub-soil, and uncropped. Thermometers are fastened in the hollow ends of wooden rods, and these are placed at different depths below the surface, in closely fitting zinc tubes filled with water. The thermometers were placed at the following depths: Surface, 3 inches, 6 inches, 9 inches, 1 foot, 3 feet, 5 feet and 8 feet, and are read hourly from 7 A.M. to 8 P.M., from the first of May to the first of November. Hourly, daily, and monthly variations of the temperature were observed. The first are confined to the upper layer of soil, and are often sudden and violent. They may be caused by the shifting of the wind, clearing of a cloudy sky, a thunderstorm &c. There is a great daily range caused by absorption of heat by day and radiation at night. The range is much reduced by cloudy or rainy weather. These daily variations take place to a depth of a foot or more. The maximum temperature at the surface is about midday and the minimum shortly after

midnight. These extremes are later at successive depths, until at 1 foot they are retarded eight to ten hours, presenting the curious feature of the one-foot thermometer rising while the surface one is falling, and *vice versa*. There is a constant rise in the temperature of the soil, beginning in the spring, easily observed to a depth of eight feet. Storms and cold weather check this advance temporarily. Below three feet there was an unbroken rise from May 22 to September 1. The mean temperatures for six months—May to October, were : Surface, 66°40' : 3 inches 65°30' : 5 inches, 65°30' : 9 inches, 65°30' : 1 foot, 64°20' : 3 feet, 62°80' : 5 feet, 58°60' : 8 feet, 55°80'. At a depth of 8 feet the mean temperature was only 10°60' lower than at the surface. During the autumn there is a zone of subsoil below one foot, which is warmer than the soil above it, and this prolongs the season.

SOME trials have, it seems, been recently made by the Veterinary Instructor in British Burmah in view to testing in the case of rinderpest and anthrax the efficacy of the lymph prepared by M. Pasteur, who is experimenting in animal inoculation in Europe. On the 7th September last two cow calves, a buffalo calf, two sheep, a large elephant, a young elephant, a pony and a pig were inoculated with what M. Pasteur terms first vaccine for anthrax fever : the temperature of the animals was, with one exception, very little affected by the vaccination. The second lymph was infused on the 23rd September, but again in this case with little apparent effect. At no time were any of the animals off their feed. The prophylactic effects of vaccination with M. Pasteur's lymph were also tested to see whether it would prove effective in rendering animals proof against an attack of rinderpest. Some cases of the disease were found, and the three calves, which had previously been experimented on, were removed to the spot and again inoculated with virus taken from the body of a true case of rinderpest. The animals were inoculated more than once, and although they were herded with some cows that were recovering from a recent attack of rinderpest, they escaped without showing any sign of infection. The calves were, after a few months, taken to another spot and placed among a herd of cattle suffering from a severe outbreak of rinderpest, and were inoculated with fluid taken from the intestines and with blood from the bodies of animals showing unmistakable signs of acute rinderpest, yet the disease was not conveyed to the calves. The Veterinary Instructor, in reporting the above facts, said that it would be premature as yet to offer any opinion as to the preventive value of this system of treatment, and has been authorized to continue the experiments. The Deputy Commissary General intends having the mules under his charge vaccinated, and the Bombay-Burmah Trading Corporation, are, it is believed, going to resort to vaccination extensively in connection with their elephants at Mingyan and in the Chindwin valley forests, where they have sustained very heavy losses amongst their elephants from what they consider to be anthrax fever.

A WRITER in the *Breeder's Gazette* mentions a cross made on his father's farm many years ago, for which he claims the very best results in producing good milkers with the Short-horn form. The foundation upon which this cross was made, consisted of Red Polled cows, these being bred to a Jersey bull excellent results were obtained so far as milk was concerned, but in form the offspring of this cross partook somewhat of the hollow form of the Jersey. To remedy this defect, these heifers were in their turn bred to a good Short-horn bull. The result was a great improvement in form, while the improvement in the quality of milk was retained. The cows resulting from this double cross are thus described by the writer : "All became marked alike, red and white patches, with large white shield on the forehead. The body long, with wide hips and well arched ribs, heavy hind-quarters, but light fore-quarters ; very short legged, but very weighty animals ; large bags, producing very rich and creamy milk. When required, a bull was selected from one of the best cows in milk and shape, and in this way the stock was kept up until my father's death." * * * "The cows were always in good condition and ready when dry to put up for

feeding. They as well as the steers were equally ready for feeding and took on flesh very rapidly."

WE heard a good deal some two years ago of the steps taken in British Burmah to develop tobacco cultivation there. One Deputy Commissioner visited the hills, where the Karens are said to grow the finest description of the weed, but to fail miserably in curing it according to Western tastes. He smoked a good deal on his trip, drew his travelling allowances, we presume, and wrote a *couleur de rose* report on all he had seen. A plantation was started near Rangoon, and people were to be induced to bring there all the leaf they could grow, to be cured on the American plan. Instructions were to be given, moreover, to ensure the best varieties only being cultivated. It was thought that as the steam rice mills had encouraged the cultivation of paddy, by purchasing for cash all that agriculturists or boatmen would bring to their mills, so a factory or plantation prepared to purchase whatever leaf was brought to it for cash, would largely stimulate the planting of tobacco. Has the project failed, that we hear so little about tobacco in Burmah at present ? The local press is silent on the subject, and good Burmah cigars are as difficult to get as they ever were.

The public both in and outside of Burmah would be glad to hear something of the results of its experiments in tobacco cultivation and curing, of which we were led to expect so much. What has been the result of the experiments, and what money have they cost ? The wisest and cheapest plan in the end might be to offer a handsome premium for the first shipment of really marketable tobacco or cheroots, as has been done in Australia and New Zealand with other produce. The result of such bonuses in the colonies has been to establish several important new industries. We are not saying that the attempt of the Local Government has failed, but we should like to know something of the results of the experiments made.

"NOTWITHSTANDING the fine stores of timber which exist in many parts of the Indian tea districts, but a very small number of estates utilize them for the supply of tea chests. The importance of having thoroughly well-seasoned wood for this purpose is obvious, and has always been insisted on ; but it seems very strange that amongst the numerous species in the Indian forests, none should be found sufficiently suitable to come into universal use. I met one Assam planter who has sawmills and who goes in for supplying estates with chests, but this kind of enterprise seems quite the exception. As a rule, tea chests are made of teak from Burmah, which must be very expensive when the excessive cost of transport up to Assam is considered. Teak makes very good boxes no doubt, but I feel sure that good suitable wood could be found in India for the purpose. In Ceylon, there has been some discussion on the subject, but the difficulty appears to have been overcome, as all estates use local woods. The tree which I have found most suitable is mallebodde, if properly treated, and therein lies the secret. It is light, inodorous, and holds a nail well. It is liable to the attacks of insects, but it seasons very quickly, and, if used as soon as ready, makes capital boxes. Many other woods are well-adapted to the purpose, and are used by the companies who supply chests in Colombo ; but mallebodde is found in almost every locality where tea is grown, and hence, its suitability for the purpose in question is a matter of importance. The seasoned hal chests now advertised by the Ceylon company are very cheap, and, for estates situated near a railway station, preferable to boxes made on the spot, but for plantations with long road transport the importance of having a suitable wood near at hand is great."

A WELL known Scotch farmer has lately been conducting a series of interesting experiments in ensilage, in connection with the Highland and Agricultural Society. He has two silos, each 30 feet long by 12 wide, inside measurement, and 13 feet from the floor to the pillars, which, again, are about 5 feet high, and support a light roof of wood covered with felt. The silos, which cost £70 each, are built into a bank, so that "while the top of the solid wall at one end is level with the ground, the floor

at the other end is level with the ground there." This allows the green stuff to be shot out of the carts without difficulty, while it also facilitates the withdrawal of ensilage from a door at the lower end. The floor, walls, and pillars are formed of concrete, the walls being from 12 to 14 inches thick; the doors are formed of boards fitting closely together, so as to exclude the air and retain the moisture. Grass that had been in the silo for three weeks had a strong, slightly alcoholic smell, and was brown in colour, but on being offered to horses, together with sun-dried hay, it was instantly preferred. The pressing down of the stuff is the most difficult part of the work connected with ensilage. The process first adopted was to trample it down, and then to cover it with boxes loaded with stones and gravel. The better plan, however, was to use half-barrels, filled with water by a hose and emptied, when required, by a siphon. It was suggested, however, that a more satisfactory method still would be to employ cast-iron cisterns or vats filled with water, as these could be made to fit closely into the silo, and be raised and lowered at will by means of pulleys. The object of the experiments in Scotland is to determine whether the silos can be relied upon to provide, in all sorts of weather, succulent and palatable feeding for the ewes in spring from vetches, clover, natural grass, and green crops, thus rendering the farmers independent of turnip fodder, which is both expensive and precarious.

PROFESSOR WRIGHTSON, of the College of Agriculture, Down-ton, Salisbury, writing on root crops or corn crops, says:—It has generally been considered that 150 lbs. of roots are required to make 1 lb. of beef or mutton, and according to a consensus of opinion of good Scotch agriculturists a ton of roots will ordinarily be converted by a fattening animal into one stone of 14 lbs. of butcher's meat. When meat was worth 7½d. per lb., a ton of roots would, according to their independent but mutually confirmatory estimates, be worth 8s. 9d., and a crop of 20 tons per acre would be worth £8 15s., or, allowing 10 per cent for waste, £7 17s. 6d. per acre. If we compare this estimate with a corresponding good crop of wheat,* which we may take at 40 bushels, then at the old estimate of 7s. per bushel, the wheat crop was worth £14 per acre, and discounting this as in the case of the root crop by 10 per cent, £12 12s. per acre.

The relative values of the two crops, therefore, might be supposed to stand as follows:—20 tons of roots at 8s. 9d. per ton, less 10 per cent for waste, £7 17s. 6d. per acre; 40 bushels of wheat at 7s. per bushel, less 10 per cent. for waste, £12 12s.; difference in favour of the wheat crop, £4 14s. 6d.

Turning to the present values of the two crops, we find that one ton of roots according to the above statistics is worth 11s. 8d. per ton, and 20 tons are worth £11 13s. 4d. Discounting this as in the former case by 10 per cent, the value of an acre of good roots will be found to be £10 9s. 10d. But the value of our 40 bushels of wheat has gone down to 5s. per bushel or to £10 per acre, and if this is discounted at 10 per cent, for the sake of comparison, to £9 per acre. The relative values of the two crops have therefore completely changed, as will be seen by the following statement:—20 tons of roots at 11s. 8d. per ton, less 10 per cent for waste, £10 9s. 10d. per acre; 40 bushels of wheat at 5s. per bushel, less 10 per cent for waste, £9; difference in favour of the root crop, £1 9s. 10d.

Not only is this the case gauged by the ordinary prices of beef and corn, but farmers who are alive to the superior value of improved animals for breeding purposes will be able to take their turnips to a better market than the shambles. England enjoys a monopoly with regard to improved breeds of cattle and sheep, and all countries send to her to recruit and improve their herds. It is not likely that this will cease to be the case, as there is something in the English climate particularly favourable for the development of high-class domesticated animals, and the tendency is ever towards depreciation after they leave our shores. No such relief is to be found for wheat growers. Here we are beaten in quality, so that many corn dealers will not buy English grown wheat at all, and in any case 5s. to 5s. 6d. per bushel is the absolute limit of price. If then, we wish to know the possible value of root and fodder crops as well as of grass, we must take into account possibilities in the direction of breeding animals that will be in demand for breeding purposes.

It is not for a moment proposed that corn-growing should be given up. It appears to be a necessity of our system of farming, for if land is folded with sheep too frequently it becomes 'stained,' and the intervening corn crop serves to sweeten it. But it would be no small gain if the farming public could be made to see that those crops which have hitherto been regarded as supplemental and as mere preparations for corn crops are now really the important crops, and that it is in reality more according to fact for us to look upon the corn crops as the accessories—as the preparation for roots, purifiers of land for sheep feeding, and sources of straw for litter. Clay lands will probably be more and more generally laid away to grass, but the lighter classes of land suitable for turnips and fodder crops will continue under the plough. It is in the case of such lands that the relative esteem in which corn and root crops are held requires to be re-adjusted. The point I have attempted to bring out is simply this—that the old notion that root crops are grown at a direct loss, and chiefly as a preparation for grain crops, is calculated to promote a false system of agriculture and ought to be reversed and abandoned.

On all sides, says the *Journal of the Society of Arts*, complaints are heard of the serious consequences of the destruction of the forests of the world, and reports arrive of the attempts that are being made to improve the present condition of forestry. Delegates from various parts of the United States were present at a Forestry Congress lately held in St. Pauls, Minnesota. The President, in his opening address, stated that in Ohio, Maine, New York, and other States, the acreage of forests was constantly increasing. In some States an "arbor" day had been instituted, and in these the increase was notable. The forest acreage of the United States, however, was less than one-fourth of the total surface, a smaller proportion than in the east, west, and north of Europe. At the present rate of consumption the supply of pinewood in the Northern States would be exhausted in a few years. Forestry is taught in the State Agricultural College at Lansing in Michigan State, which is said to contain a good labelled arboratum and a large collection of native and exotic trees under cultivation. The last Legislature of New York State passed a law to encourage tree-planting, by which any inhabitant who shall transplant by the side of a public highway adjoining his premises any forest shade trees, fruit trees, ornamental trees, or any nut-bearing trees, shall be allowed, in abatement of his highway tax, one dollar for every four trees set out. Elms must be placed not less than seventy feet apart, on the same side of such highway, and no maples or other forest trees, ornamental, or fruit trees, nearer than forty feet apart on the same side of such highway.

In Mexico, the Government has contracted with Mr. Oscar A. Droegge to plant 2,000,000 trees in the Valley of Mexico, within four years from March 15, 1881, or 500,000 trees a year in such places as the Government shall choose. The contractor pledges himself to establish a number of nurseries, and to have in them each year at least 800,000 ash, 35,000 willows, 120,000 poplars, 60,000 eucalyptus, 60,000 mountain cypress, cedars, 60,000 acacias, and 180,000 of other trees. The trees are to be in plantations of from 50,000 to 100,000 each, and Mr. Droegge must maintain them for two years after the planting. Three graduates of the School of Agriculture are to be received into the nurseries each year, there to study the science of forestry. Mr. Droegge is to raise fruit and other useful trees for distribution, and he is to receive annually \$10,000 (£8,500), till the sum reaches a total of \$200,000 (£125,000). A work on arboriculture, of recognised merit, is to be translated from the German every year in order to disseminate sound views on the subject among the students and the public.

In Europe the Forestry Schools are now very numerous, and the following list of those in Austria and Germany has lately been compiled:—Austria heads the list with nine schools—viz., the Imperial High School of Agriculture and Forestry at Vienna, with six professors and 229 students; the Eulenberg School, with six professors and 251 students; the course lasting two years; the Weisswasser School, with five professors and eighty students; the Lemberg School, with twelve professors and forty students; the Aggsbach School, near Melk, with two

professors and twenty-four students; the course of forestry in the technical high school of Gratz; the Styria Forest Culture School, with three professors and twenty-six students; the Carinthia School; the Vorarlberg School. Prussia has three institutions, commencing with the Royal Forest Academy at Neustadt-Eberswalde, with a director, fourteen professors, and other assistants. The course is two and-a-half years, and the number of students about fifty-seven. The Münden Royal Forest Academy has a director, ten professors, and seventy-eight students. The Forestry School at Grosse-Schönebeck and the forestry courses to the Army Forestry Battalion are for the training of lower forestry officials. At the former school are four professors; at the latter eleven, all of them practical foresters. Saxony has a Forestry Academy at Tharand, with ten professors and assistants. In Wurtemberg instruction is given at the Royal Agricultural Academy at Hohenheim and at the University of Tübingen. In Baden the forestry department of the Karlsruhe Polytechnic has forty students. Bavaria has a forest academy at Aschaffenburg, with a director and seven professors, in addition to which are six chairs of forestry in the University of Munich; Heesse-Darmstadt has a forestry institution attached to the University of Giessen; and Saxe-Weimar has possessed one since 1808, with a director and four professors. No other countries can equal this extensive list, but France has her famous school of forestry at Nancy, and one of forest guards at Barres, in addition to several agricultural schools and agronomic industrial schools, in which forestry is taught. Russia has four schools—viz., the Agricultural and Forestry Academy at Petrovsk, near Moscow; the Agronomic Institute at St. Petersburg, with courses in silviculture; the Forest School at Lissino, and the Forest Division of the Agricultural Institute at New Alexandra. There is an Italian school of forestry at Vallombrosa; a Danish school, attached to the Royal Veterinary and Agricultural College at Copenhagen; and a Swedish forest institute at Stockholm, besides thirteen private elementary schools. In Switzerland the department of forestry forms the fifth division of the Federal Polytechnic School at Zurich, in which are thirty students.

A Spanish School of forest engineering exists at San Lorenzo del Escorial, near Madrid. The British Consul at Malaga reports that the cultivation of the eucalyptus has of late attracted considerable attention in that province, which has been deprived of all but fruit trees in order to supply the constant demand for charcoal, caused by the extensive use of this fuel for cooking purposes. Large numbers of the eucalyptus, in a healthy and flourishing state, may now be seen along the line of railway from Malaga to Bobadilla, and in other places, and they are reported to have been effective to some extent in destroying fevers in the low districts, formerly uninhabitable. These trees are also successfully used to form avenues, and afford protection from the sun on the roads near the city.

Alone, among the great countries of Europe, Great Britain is without any adequate means for the teaching of forestry, and in order to remedy this state of things the Council of the Society of Arts memorialised the Secretary of State for India. (See *Journal*, vol. xxx., p. 879.) It was suggested that by the addition of special means of teaching forest cultivation and cognate subjects at certain of the large educational establishments of the country, such as that at Cooper's-hill, the existing system of sending forest students to Continental schools might be superseded. Last month Sir John Lubbock also drew the attention of the Government to the subject of forest education in Committee of Supply.

Mr. W. Cook, of West Chislehurst, writing in *Poultry*, says:—I am often asked what the cause is of fowls laying shell-less eggs. There are several causes. I may mention three. First, from the fowls having been kept short of materials to form or make the shell. If this is allowed to go unnoticed, it is a great strain upon the fowl's system, and has a tendency to weaken the oviduct, or egg passage, where the egg is encased with shell. Secondly, from laying double-yoked eggs. This also injures the passage very much at times. I have known fowls, after producing several of these large eggs, never lay perfect-shelled ones again, while others are left very weak, and only lay them with a very thin shell, not sufficiently thick

for hatching purposes. In such cases as these, hens ought to be allowed to sit, so that the whole system has an entire rest; when this is done, it proves a certain cure to them, and strengthens the fowls very much. The third cause is when a fowl produces eggs so rapidly that three eggs may be found in the oviduct at once. The middle one is forced down on the one that will be laid first; the third, following again quickly after the second, forces the middle one out of the part of the oviduct where the shell is formed on them.

The following are extracts from an article which appears in the *East Anglian Handbook* for the present year, from the pen of Mr. R. B. Sapwell, describing the system pursued in the rearing of turkeys in Norfolk:—

Considerable difference of opinion exists as to the best age for the stock birds. Undoubtedly a two or three-year-old gobbler, and hens from two to four years old, would give the strongest and best stock; but I find the disadvantages arising from keeping old birds so great that I almost always fatten my stock birds and bring up young birds for the next season, saving only especial favourites for a second year. The advantages, I believe, gained from using young birds are that the eggs produce a larger number of gobblers than from older birds, and these are much more valuable than hens, and I find young hens commence to lay ten days or a fortnight before older birds. The young gobblers are not so savage as the older ones, and fewer hens are injured and killed by them.

Hen turkeys generally lay about twenty eggs. It is a good plan to set the first eggs under hens, giving the turkeys about fifteen of their own eggs to sit upon. It is an unwise, as well as a cruel, plan to set all the turkeys' eggs under hens, and make her lay all the season. Late-hatched turkeys never thrive as the early birds do, and they never grow to a size to realize a profitable price. The turkey's services are lost to her own offspring, for turkeys rear their own young much better than hens do, and it almost invariably happens that a turkey becomes so debilitated by laying all the spring that she wastes away and dies in moulting. The time when turkeys require the greatest care is until they are six weeks old, when the young cocks begin to show a little red on their heads. Dryness is of the first importance; large, roomy coops, with covered runs, are desirable, that the young birds be not allowed to roam about in wet weather, or when the dew is on the grass.

The food for the newly-hatched birds should be principally hard-boiled egg, with dandelion, lettuce, onions, or nettles chopped up, with a little bread-crumbs; to this may be added a little rice boiled in skim milk (if quite sweet), a little suet or greaves, and in wet and cold weather a little cayenne pepper, with grain of all sorts as the birds grow older. A fresh site for the coop every morning is a *sine qua non*, and a little exercise if the mother is a turkey—but not if she is a fussy old hen—is also advantageous as the chicks get on. A good sign is to see the young turkeys catching flies. In order to get fresh, untainted ground, it is a good plan to hurdle off a part of a field—a new ley, if handy, for the coops, and the grass should be kept mown closely to the ground.

Turkeys will take to any young turkeys, whether hatched by themselves or not; so when our young birds get fairly strong, we generally transfer those hatched under hens to the turkeys. One has to be careful that the chicks do not perch on the rails of the hurdles or the tops of the coops; crooked breasts would be the inevitable result; they should be induced to sit on the ground as long as possible, and then taught to perch in low bushes and trees, and until they are shut up for fattening they are better never to have entered the fowl-house. Having reached the age of two or three months, June has arrived, and the birds are perfectly hardy, requiring little care, but generous feeding. A more economical food is now desirable, and barley-meal, with, perhaps, a little scrapcake, maize, barley, and small wheat, is the usual food.

Turkeys for Christmas should be shut up in a light, dry roomy house the first week in November; troughs with as much maize and good barley as they can eat should be always by them, with two good meals a day of just as much barley-meal, mixed with fat milk, as they can eat, and milk to drink

Sliced mangel, turnips and swedes, and cabbage are useful and necessary, and plenty of sand, lime, ashes, and brick-dust should be in the corners of their house. Let the troughs be well cleaned every morning, all surplus food removed; on a farm there are plenty of other fowls glad to clean up after turkeys. In conclusion, let me strongly advise my readers never to make birds of their own breeding with one another; every year let them purchase a new bird for stock, unless they retain the old bird and are not using hens of his breeding. There is no economy in buying a cheap bird; a few shillings extra expense about the gobble will probably be a matter of three or four pounds weight in each young turkey next year.

TWENTY-ONE years ago, says a writer in the *Farmers' Review*, Congress gave each State public lands to the extent of 30,000 acres for each member of Congress, senators and representatives included, according to the census of 1860, for, in the language of the Act, the "endowment, support and maintenance of at least one college, where the leading object shall be, without excluding other scientific and classical studies, and including military tactics, to teach such branches of learning as are related to agriculture and the mechanic arts." This Act originated with Hon. Justin S. Morrill, of Vermont. Before entering upon public life he was a merchant and farmer in Strafford, the town of his nativity, where he came into close contact and profound sympathy with the agricultural and working classes of the people. Being a man of native shrewdness and great common sense, with an aptness for public discourse, he easily became a leading man in the community, and entered Congress about 1856, if our memory is not seriously in error. His intensely practical and patriotic turn of mind suggested this eminently wise use of the national public domain, then and since so lavishly, if not recklessly, bestowed upon projected railroads. Many remember the various plans adopted by the different States in disposing of the proceeds of these grants. That many mistakes were made is true, and it could not be otherwise, and that some of these colleges are following more or less defective policies to-day is true. But with all these errors, our serious thought is one of wonder and gratitude that the errors are so few and limited in their baneful influence.

There lie before the writer the catalogues and connected reports of three of these colleges—those of Massachusetts at Amherst; New York, the Cornell College at Ithaca, and Kansas at Manhattan. These colleges may be taken as representatives of that class of schools in the land. Cornell, most wealthy and ablest manned of them all, stands among our agricultural colleges very much as Harvard, Yale, and John Hopkins University do among the classical schools of the country. Amherst represents those which seek to combine the classics, agriculture, and the mechanic arts especially, those relating to manufactures. This latter feature is worked or taught in Boston as a portion of the land grant was bestowed on the Institute of Technology a school whose specialty is in this line. The Kansas College is almost wholly "practical," agriculture, manufactures, telegraphy, printing, and the allied sciences; no Greek or Latin is mentioned as belonging to its curriculum. At Cornell there are some four or five general courses of study, those of art, of literature, of philosophy and of science, and these are sub-divided into as many as ten special courses of four years each, so that the student who wishes to pursue a course purely agricultural, finds a full four years of such study laid out with classes pursuing it. Or, if he wishes the mechanical arts or architecture, or civil engineering, or chemistry, or other special courses, he finds them. The Massachusetts College, partly from more limited resources and partly from the traditions of New England, has a less varied course and one more strongly marked by its classical features, though giving thorough instruction in agriculture and the mechanic arts. The Kansas School fairly represents the earnest, vigorous, pushing and "practical" spirit of our western civilization. That it really represents the popular sentiment of the people may be seen from the fact that on its catalogue last year were enrolled 347 names. Amherst had 110 students, but among them were two specialists, one from Brazil and one from England. Cornell had 410 students, a large number of whom were pursuing special and post-graduate studies, while the

field of its patronage embraced Brazil and Japan, as well as nearly or quite every State in the Union.

THE wild plantain it seems is not found in the Kistana, Nellore, Bellary, Anantapur, Chingleput, North Arcot, South Arcot, Salem and Trichinopoly Districts; it is believed to exist on the Nallamalai Hills in Kurnool; it is found in small quantities in the forest uplands of Ganjam and on the Anaimalai Hills in Coimbatore, and very sparingly in the sholals and by the rivers and streams of all the forests of the Periyakulam range in the Madura district. On the Western Ghats of Malabar it is widely distributed, but is by no means abundant; there are large quantities in the Raynagadda and Jeypore tracts of Vizagapatam and in the Rumpa, Rékapalle, and other uplands of the Godavari; the ghats of South Canara could supply from 15,000 to 20,000 trees a year: it is found on the hills of Tinnevely, but not abundantly. The reports from the Nilgiris are conflicting, they are three in number; in the first, the Collector, after consultation with gentlemen settled in different parts of the hills, concluded that the wild plantain "did not grow in the Nilgiri district in any considerable quantity"; the next report forwarded by the Collector was from Colonel Jago, the Deputy Conservator of Forests, who stated that the wild plantain "grew abundantly in the vicinity of Devála and Cherambádi, in the south-east Wynnad, and on the slopes below Thiamalai and Nunjappa Rao's estate on the Kartary side; the third report, that of the head Assistant-Collector, confirmed that of Colonel Jago in saying that the wild plantain "grew in great abundance on all the slopes of the ghats between Wynnad and Malabar, and was found in great quantity on all the estates lying on the edge of the Wynnad plateau."

THE following letter from Mr. W. R. Robertson, to the Director of Revenue Settlement and Agriculture, may be interesting:— I have the honor to reply to paragraph 4 of the Board's Resolution, No. 1334, of the 13th May. In the United States of America, the desirability of extracting the oil of cotton-seed has long been recognized, and experiments in extracting the oil were instituted as early as 1826; but it was not until 30 years later, when experiments were made by first decorticating the seed and pressing the kernels only, that any really satisfactory results were obtained. Previously, experiments had been made with the whole seed, and from the lint adhering to the seed absorbing so much of the oil, it was found almost impossible to remove enough oil to make the undertaking profitable. At the present time, the extraction of cotton oil affords employment to many very extensive, fully-equipped manufactories, engaged solely in the industry. The following extracts from a report by Mr. Sypher, an American authority on the question, affords full information regarding cotton-seed manufactories and the processes followed in the extraction and preparation of the cotton-seed oil:—

"A proper mill for the manufacture of oil and oil-cake from cotton-seed should consist of a substantial building having three and-a-half stories and basement, one hundred feet long by forty to fifty wide. The engine should have power in proportion to the proposed capacity of the factory—twenty horsepower, if two pairs of five-box hydraulic presses are used. The hydraulic presses must be placed on a firm foundation, carefully laid. Heaters and rollers are machines made by the same machinists that supply the presses and pumps. Of hullers—the machines that bear the same relation to oil that gins do to lint—there are two or three patterns that will do the work, though the best, because it is least liable to get out of order and has a much greater capacity than the others, is one invented by Abram J. Sypher, for some time an Engineer in the United States Navy. This machine is in its appearance, in its operation, and manner of receiving seed, somewhat similar to a wheat thresher. The seed is delivered into the huller by an endless canvas apron; it passes under a cylinder revolving at great speed, armed with steel blades, and surrounded about two-third's way by a concave box also armed with corresponding

knives. As the seed is forced between these, the pericarp or hull, is broken and forced from the kernel. The mass of crushed seed then falls into a great revolving sieve. The kernels, many of which are broken into fine pieces, pass through the meshes of the wire sieve, and the pericarp, to which the lint adheres, is carried away and delivered into the fire-room, where it is burned under the boilers and affords a full supply of good fuel for the use of the establishment. The clean seed is now carried by means of a system of elevators to the attic-story, and then passes down into the crushers or rollers. These consists chiefly of two rollers revolving towards each other with unequal velocity so geared as to produce both a crushing and a tearing effect upon the seed. The meal, as the seed is now called, falls to the bin on the first floor, and is shovelled into the heater by the pressman's attendant. The heater is a short, double cylinder, so arranged as to heat the meal in the inner cylinder by steam, which circulates in the space between the inner and the outer walls. Here the meal is heated until the water is converted into steam and escapes; the hot meal is then placed in wedge-shaped bags, made of woollen duck; these are placed in hair books, which slide into the boxes of the press. As soon as the pressman has filled all the books, the pump is set working and the tremendous power of the hydraulic press soon forces out the liquid oil in warm, gushing streams. Seven minutes up, and the press returns; the books are thrown out, the duck bags are stripped from the meal, now pressed into solid cakes, the cakes are set up in racks to dry, and thus the operation is completed.

"From the seed which was thrown into the huller, two merchantable articles are produced at the press—crude cotton-seed oil and cotton-seed cake. After the oil has cooled down to atmospheric temperature, and the floating impurities have separated from it and settled to the bottom of the tank, it is of a deep red color, and weighs about seven and-a-half pounds to the gallon. This quality of oil found a market among oil refiners, who, usually by very simple processes, removed the mechanical impurities and destroyed the coloring matter so as to produce an oil of a rich olive color, sweet and agreeable to the taste. Much of this found its way to the tables of our first-class hotels and private families. As a substitute for olive oil, it has no equal, and when flavoured by the addition of genuine olive, it is much superior to any other adulteration yet produced. The chief consumers of the cotton-seed oil, however, are the soap-makers. The oil was purchased by manufacturer in its crude state, and from it was produced almost every grade of soap, from the cheapest family to pure white Castile and the finest and most highly perfumed toilet soaps.

* * * * *

"The refining process is simple, and, after a little practice, may be successfully conducted by any one possessed of ordinary skill. The agent employed to remove the impurities is a solution of the soda ash of commerce, having a strength of about 30 degrees. The oil is put into a large metal tank, supplied with steam pipes for heating, and with proper apparatus to keep the oil thoroughly agitated. The caustic solution and the oil, when mixed, should be at the temperature of the atmosphere in the factory, and about one gallon of the solution should be put into ten gallons of oil, mixed small quantities, at intervals of a few minutes. The mixture should then be slowly heated up to 100 degrees, then allowed to cool. During the pouring in of the solution, and while the mixture is being heated, and until the temperature has gone down nearly to its natural state, the stirring apparatus should be kept in motion. The oil should then be left in the tank at least 24 hours that the impurities may settle to the bottom; then, by a faucet inserted at a distance of several inches from the bottom, the refined oil may be drawn into a wooden tank placed in the basement, where it will sink to a still lower temperature, and deposit a purer sediment in the bottom of the tank. If the process has been conducted with care, the refined oil will be perfectly clear, and of a rich olive color. The price of this quality of oil before the war rated at from sixty to seventy-five cents per gallon.

"The ground seed, from which the oil has been expressed,

is known to commerce as 'cotton-seed cake,' and is consumed principally in feeding cattle. It is classed by general feeders with linseed cake, though chemists and scientific dairymen claim for it a superiority. When fed to milch cows, it increases the quantity and improves the quality of the milk; it is a rapid flesh former, and the manure of the stock yard where cotton-seed meal is fed is of a very superior quality."

I thought that a small experiment in the extraction of the oil of cotton-seed might be instituted at the Farm with advantage, and I accordingly had an experiment made, the results of which are shown in the enclosed statement. The seed used was New Orleans; it is somewhat larger than the seed of indigenous cotton, but is similarly covered by adhering lint. I forward samples of New Orleans cotton-seed and indigenous cotton-seed. To get rid of the husk with its adhering lint, the seed was crushed in an ordinary bean mill and sifted; the mill not being adapted to the purpose, the process was tedious and slow; for decorticating the 170 lb. of cotton-seed, the cost amounted to 15 annas and 8 pies—about 9 annas and 3 pies per 100 lb. of cotton-seed—a high cost, but it must be remembered that the work was novel to the workmen, while the decorticating arrangements were imperfect. One hundred pounds of cotton-seed yielded 34 lb. of decorticated seed. An oil mill not being available at the farm, one was hired, and the hire that had to be paid was at least double the usual rate. One hundred pounds of the decorticated seed yielded at the rate of 4 measures and 7 ollocks or 16 lb. and 15 oz. of oil, and 71 lb. of oil-cake. The expenses were as below:—

| | Rs. | A. | P. |
|--|-----|----|------|
| 170 lb. of cotton-seed at 50lb. per rupee | ... | 3 | 6 5 |
| Expenses of decorticating the seed | ... | 0 | 15 8 |
| Hire of the oil mill, with cattle labor, &c. | ... | 0 | 14 0 |
| | | 5 | 4 1 |
| | Rs. | A. | P. |
| Deduct value of 29 lb. 4 oz. of oil-cake at Rs. 10 per candy | ... | 0 | 0 4 |
| 107½ lb. of husk at Rs. 4 per candy | ... | 0 | 13 8 |
| | | 1 | 7 1 |
| | | 3 | 13 0 |

Thus the net cost of the oil, of which there was two measures—6 lb. 15 oz.—from 170 lb. of cotton-seed, was Rs. 1-11-6 per viss, which is much beyond its value; however, as I have already pointed out, it could not have been expected that the experiment would be commercially successful. The results, however, show that the extraction of the oil is quite feasible, after the seed has been decorticated, and I have no doubt but that with suitable machinery and arrangements, the oil can be extracted at a sufficiently low price to enable it to compete in the market with other oils. I forward samples of the oil-cake and oil; the former contains much oil which a hydraulic press would remove. The oil, it will be noticed, is unrefined. In the United States, 1 ton of cotton-seed is said to produce 35 gallons of oil and 750 lb. of oil-cake. In the experiment just recorded, the outturn per ton of seed was only 10 gallons of oil and 395 lb. of cake; it is evident, therefore, that a considerable proportion of the kernels of the seed was, in the Farm experiment, removed with the husks.

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The usual Meeting was held on Wednesday, the 26th September 1883.

W. H. COGSWELL, Esq., President, in the Chair.

THE proceedings of the last meeting held on the 29th of August were read and confirmed.

The following gentlemen, proposed at the last meeting, were elected ordinary members:—

Mr. M. N. McLeod, Pipra Factory, Chumparun.
Baboo Radhika Prosad Mookerjee, District Engineer, 24-
Pargunnahs.

The Manager, Rangit-Rangit Tea Company, Darjeeling.
Mr. C. B. Mackenzie, Gajilliduba Tea Estate.
Mr. A. Ross, Shahabad.

The names of the following gentlemen were submitted as desirous of joining the society:—

General Asimuddin Khan, Rampore State, vid Moradabad,—proposed by R. Deay Spedding, Esq., C.S., seconded by Major D. G. Pitcher, B.S.C.

The Manager, Bowbakeh Company Cotton Mills, Limited,—proposed by the President, seconded by J. C. Murray, Esq.

The Manager, Fort Gloster Jute Manufacturing Company, Limited,—proposed by the President, seconded by J. C. Murray, Esq.

Rejoined.—Mr. F. Farquharson, Noonmattee Tea Estate, Assam.

A quantity of Aster Seed, French and China. From C. Nickels, Esq., Jounpore.

About 20 lbs. of Maize Seed, from the Cape per Rautenbern, Captain Crudaose. From S. R. Elson, Esq. The thanks of the Society were voted for the above contributions.

COMMUNICATIONS.

Early Amber Sorghum.

Mr. Helps, of Rangli-Rangliot, writing on the 17th and 25th September, says that the early amber cane, sown in May and June, is from 5 to 7 feet high, but not thicker than his little finger; it is in full flower, and has much the appearance of the "jowar" grown in the Punjab. Mr. Helps goes on to say:—

'I shall be very glad to give the "sorghum" seed another trial, and I think if sown a month earlier will be a greater success than what I put down this year.

'The "sorghum" seed you sent me last May I put out at two different times, end of May and beginning of June, the success of the first sowing inducing me to try the second, but, most unfortunately, a day or two after the second sowing very heavy rain came on, and washed nearly all the seed away, besides doing a deal of damage to the young plants I had up from the first sowing; the plants were only a few inches high and delicate, but by sowing a month earlier I think they would be strong enough to resist any rain. I, moreover, think that it is the proper season of year for sowing the seed here, judging from the way the first came up so well. My difficulty will be in getting the cane pressed, for there are no mills in these parts, but I will do my best, and if I can manage it, I will get a carpenter to make me a rough one just to try and make "goor" and "rab" as you wish; but I should like to have a few instructions sent me as to how it is done, as I have no idea myself.' I noticed the cane contained a deal of saccharine matter. Elevation at which grown is, I think, about 4,500 to 4,600 feet.

'This is a very good elevation for potatoes, and they grow well here; so if you have any good seed I would not mind trying a few maunds if you could send them up. I would send you part of the crop, if successful.'

Herbert Finch, Esq., Mewnah Estate, Shajehanpore, in a letter, dated 17th September, says:—

'The early amber sugarcane seed you sent me was sown on 15th July, and is now seven feet high and in seed. The quantity is too small to admit of any practical experiment as to its value for producing sugar, but the rapidity of its growth would alone make it of value as an intermediate fodder crop for elephants and cattle. Experiments made with very small quantities of seed are practically useless. It would take some four maunds of cane to make a boling, the result of which could be depended on. If you will send me four or five pounds of the seed, I will sow it in March next.'

A few lbs. of seed have been sent to Mr. Finch for trial. From Kourer Jai Narain Singh, Didwary, Moradnugger, 23rd September:—

'The proper season for sowing the early amber sugar-cane appears to be during the months of May and June, for then the crop would come up along with the country Sugar-cane in November and December, which is the proper time for pressing the juice. I will, however, sow a small plot of ground just now to see if the plants come to maturity in December or January, in which case a second crop can be obtained.

'Captain J. F. Pogson supplied me with the seed I sowed in March last, and the canes became fit for pressing in June, which was done by means of a *Beke* sugarcane Mill, but as the weather was extremely hot, the juice did not crystallize and produce saccharine matter sufficient to form into sugar.

'As you have now been good enough to supply me with a large quantity of seed, I will try my best to give it the fullest trial possible; and communicate to you in detail the result of my success

or otherwise.' Captain Pogson, writing on this subject under date 6th September, says:—

'In my letter, I asked you to send me a sample of the "broom corn," in order that I might ascertain what it really was. I see our common "bajra" is in America called "pearl Millet." The "doorn" turns out to be a new or unknown variety of "jowar" (*Aeluropus*), and I strongly suspect the "early amber sugarcane" is the "Impee," or Chinese sugar sorghum improved by cultivation.

'I think it would be a good plan for the Council of the Society to sanction an indent being made on China for all varieties of sugar-producing sorghums.

'Johnston says:—"In China under the name of 'sugar-cane of the north,' a species of sorghum is cultivated for the extraction of sugar. This plant was introduced into France by M. Vilmorin, who states from his experiments that it is capable of yielding, on an average, from an acre of land 26,000 pounds of juice, containing from 10 to 13 per cent of sugar, and that this is more than the average yield of the sugar beet. It is alleged, however, that the plant is adapted to only a few parts of the south of France."

'I believe the far-famed sugar-candy of China is made from the sugar obtained from this variety of sugar sorghum, which may be a very superior variety of "Impee."

'The Chinese are not given to parting with these best varieties of seeds at once, and I dare say the "Impee," obtained over 40 years ago, was a common kind. The mere fact of the true sugar sorghum coming from the North of China, shows that it is an inland plant, grown in a cool or cold climate. Our knowledge on the subject is very scanty, and should be increased, and it would be a great point gained if the Chinese method of making sorghum sugar and sugarcandy was ascertained.

'At the Cawnpore Farm, the "early amber cane" gave an "intensely acid" juice, and pot extract or "goor" to correspond.'

The Secretary, in reply to Captain Pogson, drew his attention to the proceedings of the Board of Revenue, Madras, in which Mr. Robertson, the Superintendent of Government Farms, says of the Minnesota early amber sugarcane:—"This is a variety of sorghum which originated in the State of Indiana in 1860, from a plant which appeared in a crop of Chinese sorghum. The seed of this plant was sown, and the produce again sown, which, having been repeated for several years, a large quantity of the seed has been produced."

Captain Pogson's suggestion was approved of, and the Secretary was instructed to put himself in communication on the subject with any correspondent the Society may have in China.

MESEMBRYANTHEMUM CRYSTALLINUM.

From Major S. S. Jacob, dated Jeyppore, 1st September:—

'In the *Scientific American*, dated 21st July 1883, a notice appears of the above plant, that M. Herve Mangon had observed that it takes up from the soil an extraordinary quantity of alkaline salts, and that he had proposed to employ it for removing excess of salts from land on the sea coast, and in salty deserts, so as to make the land gradually fit for ordinary vegetation.

'I write to ask if you have information about this plant, and if it has not been tried in India, to suggest to the Agri-Horticultural Society the advisability of getting some of the seed and distributing it for trial in this country, especially in the districts where red lands occur.

'I shall be happy to give it a trial if I can be supplied with some seed.'

In his reply to Major Jacob, the Secretary mentioned that the *M. Crystallinum* is the 'ice plant,' so called in consequence of every part of the plant being covered with small watery pustules, which glisten in the sun like fragments of ice. Large quantities of this plant are collected in the Canaries, and burnt, the ashes being sent to Spain for the use of glass-makers (Lindley and Moore). *Meembryanthenum Crystallinum* in Spain and *M. Coticum* and *Nodiflorum* in Egypt, are collected for the purpose of furnishing alkali for glass-works: the former is called Barilla Moradeva by the Spaniards, who import large quantities of its ashes from the Canaries, where the seed is eaten as a common food, according to Broussonet (Lindley, Vegetable Kingdom). *M. Nodiflorum* is used at the Cape in making morocco leather (Simmons). Major Jacob's attention was drawn to the *salicaria* plant, which has some of the same properties as the *Meembryanthenum*. The Secretary was directed to endeavour to procure some seed of both plants.

RICHARD BLECHYNDEN, Junior,
Deputy Secretary.

OFFICIAL PAPERS.

ANNUAL REPORT OF THE ROYAL BOTANIC GARDEN, CALCUTTA, FOR THE YEAR 1882-83.

THE past year has seen the completion of most of the improvements in the garden grounds which were sketched out by me for the approval and sanction of Government in the year 1874. It may therefore not be out of place to give here a short résumé of what has been done, for during the nine years that have elapsed since these proposals were submitted, the garden has been practically re-made. The whole extent of the grounds has been raised in level, the necessary soil having been obtained from large sheets of ornamental water which have been cut out. Thags artificial

lakes have been connected with each other by underground pipes, and a steam pump has been supplied, by which the water in the whole system can be kept at a high level by means of water pumped up from the river. Numerous wide roads have been made all through the garden, so that carriages may now be driven through every part of it. This is an improvement which is much appreciated, as the old restriction to driving acted to a great extent as a deterrent to visitors. Numerous foot-paths have also been made. The bamboo-and-mat erections, which used to do duty as conservatories, have been replaced by three large, handsome, and efficient structures of iron, on which a thin thatch of grass is spread, and under shelter of which tropical plants thrive admirably. The valuable collection of dried plants has been suitably housed in a handsome building designed by Mr. E. J. Martin, the Government Architect, the internal arrangements of which are to a considerable extent adapted from those of the new Herbarium building at Kew. New propagating houses, tool, and potting-sheds have been erected, and good dwelling-houses have been built for the members of the garden establishment, both European and native. A boundary wall and ditch have been partly built round the garden; and, finally, attempts at landscape effects have been made in the garden, the collections have been increased by considerable accessions of plants, both indigenous and exotic. The collections still, however, require strengthening in many important respects, and certain minor improvements still remain to be carried out before the garden is in the condition I should like to see it.

2. The garden still remains comparatively inaccessible to the public, and there can be no doubt the number of visitors would be largely increased were it connected with the new road recently made by the Port Commissioners along the river bank between the bridge at Howrah and Shalimar. At present this new road ends at Shalimar, and the end of it is not even connected with the old road to the garden, through Seabpore, so that for a visitor to this garden or to the Engineering College the new road is not only useless, but misleading.

3. *Economic Plants.*—Attention has been given during the year to various economic plants. The Coara rubber tree has been propagated and distributed to a considerable extent. This species grows quickly and thrives well. It is, however, rather easily blown down or broken by the wind, especially during wet weather. The seedlings of the Zanzibar rubber plant (*Landolphia*), for the introduction of which we are indebted to Sir John Kirk, are growing rapidly, and this species appears to have found a congenial home in Lower Bengal. Mahogany seedlings continue in steady demand. The paper mulberry (*Broussonetia papyrifera*) grows wonderfully well, and I am trying to obtain the seed in large quantity from Europe so as to be able to spread its cultivation in India. A few small plants of the species of *Oncamon* yielding the Cassia bark of commerce were received during the year from Mr. Ford, of the Botanic Garden, Hong-Kong. I regret to say that these do not promise to thrive very well here. Every care is, however, being taken of them. The food-plant known as the Soy bean has been a good deal written about lately, and its cultivation has been pressed on people in this country. More in obedience to the loudness of this clamour than from a belief in its soundness, I have arranged for a supply of Soy beans from Japan, and I propose to distribute these pretty extensively for trial.

4. *Fibrous Plants.*—During the year the utilization of various fibrous plants has received my attention. At the request of Sir Walter DeSouza, permission was given to Mons. A. Berthet, of Rouen, to erect in the garden his patent machine for cleaning reeds and other fibres. This machine was set up and worked under the supervision of a French mechanic sent out by Mons. Berthet. It was driven by the garden engine, and fibre-yielding plants of every kind available were tried in it. The machine is primarily adapted for reeds, which fibre, as also Agave, it cleans admirably. For plantain fibre it is less suitable, but with certain alterations it might be adapted to that fibre. For *Hibiscus tiliaceus*, a common Sunderband plant, which I tried in it, it is also not quite suitable. The machine is beautifully simple, and I have little doubt its ingenious inventor, were he to give his mind to the subject, would have no difficulty in contriving simple and cheap machines adapted to any native fibre which on trial may prove suitable as a raw material for paper, or for cloth, or rope. The experience of the past year confirms me in the belief that plantain fibre will one day come largely into use in India as a raw material for paper; and as plantain stems and leaves are at present absolutely waste, the utilization would be a gain to the country. In several former reports I have referred to the leaves known by the vernacular name *bhabur* as the produce of *Eriophorum comosum*. I have now satisfied myself that the bulk of the *bhabur* used by natives for rope-making is not derived from *Eriophorum* as I had supposed, but from *Andropogon inodorus*. This grass, I find from enquiry locally made, abounds in the hill parts of Behar and Chota Nagpore, where it is known as *Sabat*. From these regions it can be obtained in quite considerable enough quantity to make its utilisation as a paper material a feasible project. And the people who actually collect it sell it at a reasonable enough rate. But in order to get it brought to Calcutta in sufficient quantity for local manufacture, or for shipment to Europe, middlemen have to be employed, whose ideas of profit are pitched so high that, until they become modided, the utilisation of *bhabur* must remain in abeyance. This is only in accord with the common experience in the mofussil, that competition in trade is not sufficiently keen to have much effect in keeping down prices; but that, on the contrary, traders still form guilds banded together to enhance prices, even at the risk of cooking off demand.

5. *Introduction of Gourami Fish.*—Through the kindness of the Hon'ble H. S. Thomas, of the Madras Civil Service, one of the garden tanks has been stocked with fry of this excellent Chinese

fish. Should this species be found to thrive in Bengal, I propose, with the sanction of Government, to make use of the various ornamental lakes in the garden as breeding grounds, so that fry may be raised for distribution to all parts of the country. The expense of arranging this would be extremely small, and could easily be covered by making a small charge for the fry.

6. *Herbarium.*—Since my last report the new building for the Herbarium has been completed and made over to me by the Public Works Department. This structure, being built on open flue arches 7 feet high, is well raised above the ground, and ought to be perfectly dry. Internally it contains a single room, 115 feet long by 44 feet broad. Round the sides and ends of this room there run, at 11 feet from the ground, a continuous gallery 15 feet wide. The gallery is connected with the floor by three spiral staircases, and the two sides of it are connected with each other at the middle by a bridge, which affords a means of communication between the two sides without the necessity of going round by the ends. Except the fittings of the doors and windows, which are of wood, the building is composed of masonry and iron. It is therefore practically fire-proof. The Herbarium and Library have been removed to this building, and the short experience I have had of it leads me to believe that it is well adapted in every way for its purpose. The old building in which the collections were previously accommodated (in addition to its other faults) was hopelessly small, and in it the collections were so crowded that it was difficult to consult them. Moreover, a considerable proportion of the collections, which it was absolutely impossible to find room for within it, had to be accommodated in my own house. In the new building there is ample space, and by the purchase of 24 new cabinets it has been easy to arrange the whole collections, so that they may be consulted with facility and comfort. The additions to the collections themselves during the year have been considerable. From the Malayan Peninsula, Herr Kunstler has sent a number of valuable and excellently prepared specimens; from Dr. George Watt, lately on special duty in Manipore, I have received a set of specimens illustrating the Flora of that most interesting frontier country. Mr. J. S. Gamble has contributed a number of dried plants from the northern parts of the Madras presidency, and Mr. W. A. Talbot, of the Forest Department, has sent a number of fine plants from North Canara. Mr. J. Marshall Woodrow, of the Botanic Garden at Poona, has sent some interesting specimens of Decoan plants. Dr. Schlich, Inspector-General of Forests, and Mr. Hope, late of Dehra Dhoon, have sent interesting contributions from Northern India. To Dr. Treub, Director of the Botanic Garden of the Dutch Government in Java, I am indebted for some specimens of rare oaks, laurels, and figs; and I have to thank Dr. J. Anderson, F.R.S., Superintendent of the Indian Museum, for an interesting collection of Mergui plants gathered during a visit made by him to that province. A considerable number of specimens were also brought together by native collectors whom I despatched to the higher Sikkim Himalaya.

7. *Interchange of Plants and Seeds.*—The issues of living plants were 29,493, as against 23,939 last year. Packets of seeds to the number of 5,224 were also despatched, as against 3,303 last year. These plants and seeds were for the most part given to magistrates for planting in stations and along roads; to superintendents of hospitals, jails, and educational institutions, and to municipalities. On the other hand, there were received, from various contributors in this and other countries, 9,796 living plants and 883 packets of seeds. Chief among the contributors have been Sir J. D. Hooker, K.C.S.I., C.B., R.F.S., &c., of the Royal Garden, Kew; the Directors of the Botanic Gardens in Ceylon, Ceylon, Jamaica, Hong-Kong, Natal, and Singapore. Beautiful collections of Malayan plants have been sent from the Malayan Peninsula by Mr. Kunstler, and of Andaman plants from Mr. E. H. Man of the Andaman Commission. The garden has been, during the past as in former years, indebted to the kindness of Messrs. Apcar and Company for free freight on many packages of plants and seeds received from the Malayan Archipelago and from China.

8. The Herbarium has throughout the year been in charge of Mr. L. J. K. Brace, who has worked with much energy and enthusiasm. The removal of the collections from the old to the new building was carried through by him without damage to a single specimen. During the year Mr. J. Craig filled the office of Curator of the garden; but since the close of the year he has been dismissed for misconduct. The Assistant Curator, Mr. G. Urquhart, conducted his duties throughout the year to my satisfaction; as also did the native overseer Baboo Prosunno Coomar Sein, and the head males in the several departments.

9. The budget allotment for the year was Rs. 70,350, and the whole of it was spent. The receipts from sale of surplus plants were Rs. 1,494'10-8, which sum was paid into the treasury.

10. *Lloyd Botanic Garden, Darjeeling.*—In my last report I stated that this garden was being preyed upon by myriads of cockchafer grubs. During the year now under review these creatures continued their depredations until they killed pretty nearly every plant the garden contained. This grub feeds on the fine rootlets by which plants absorb their nourishment from the soil, and only such plants escape as send their rootlets deeper into the soil than it cares to penetrate. The whole of the grass in the garden and all herbaceous plants rapidly succumbed to its ravages, as did many of the flowering shrubs, only the deeper rooting shrubs and trees being spared. Even the plants in the conservatories did not altogether escape; eggs of the insect having got in considerable numbers into the soil of the pots. This grub is not new to the district. It is often found in soil near the sites of old grazing stations in the forest, and it not infrequently does damage to native crops in the neighbourhood of these. The cockchafer, of which it is the grub, appears thus to affect manure. And there is little doubt that the abundance of the grub in the Darjeeling garden is due to the fact that the whole of the hill above the

garden is saturated with the sweepings and filth of the station, which the municipality continued, in spite of many protests, to bury there for long after the garden was formed. The alterations on the top of the hill, necessary for the preparation of the site for the Eden Sanitarium, were also a fruitful cause of injury to the garden. Heaps of loose debris were shot over the side of the hill from the hospital site, and during the past two years quantities of this debris have occasionally rushed down the steep slopes above the garden, carrying a proportion of the municipal manure with them and spreading themselves over large pieces of the garden. Mr. Jaffrey, the Curator of the garden, made vigorous efforts to conquer the grub, and about six millions were collected and destroyed by the garden labourers under his supervision. This plague now shows signs of disappearing; and as suitable means are at last being taken to prevent further slips from the hospital hill, the prospects of the garden for the year now entered upon are therefore decidedly brighter. The acclimatized English potatoes produced in the garden last year were largely distributed in the district for seed, and it is believed that the quality of potatoes in the district generally has, by these means, been to some extent improved. The budget allotment of this garden for the year was Rs. 8,830, the whole of which was spent. The receipts, Rs. 355-4-3, were paid in as Government revenue. Mr. Jaffrey has worked with much energy and pluck under disheartening circumstances, and he is now beginning to re-plant the denuded flower-beds and grassy slopes which two years ago looked so pretty.

NOTE ON THE CULTIVATION OF SUGARCANE AND THE MANUFACTURE OF SUGAR IN ASSAM.

(By the Director of Agriculture.)

A.—THE BRAHMAPUTRA VALLEY.

THE varieties of sugarcane in the valley of the Brahmaputra are not numerous, and may be ranked as follows in the order of their importance:—

1. *Bagi* (white) or *mugi* and *mag* (amber-coloured).
2. *Rangi* (red), *kali* (black), or *teliya* (i.e., the colour of newly-expressed mustard-oil).
3. *Bengal* or *Bombay* cane.
4. *Mulaka* and *magara* or *megala*.

The two first kinds are regarded by the natives as indigenous. They are commonly grown together, either intermixed at random, or with red cane disposed round the edges of the field as a protection of the more valuable yellow cane against the depredation of men and animals. A well-cultivated field of *mugi* stands about seven feet in height, and the canes measure a little more than an inch in diameter at the thickest part; the colour is an amber yellow, and the texture soft and juicy. The *teliya*, on the other hand, is hard and thin, of a deep red colour, often passing into a dark shade of purple, whence its name *kali*, or black; and the average dimensions of the stalk do not exceed five or six feet in length by three-quarters of an inch in diameter. These two varieties of cane are more largely grown than any other, the *mugi* being recommended by its superior qualities as a sugar-producer, while the hardness and unattractiveness of the *teliya* render it well adapted for the careless style of cultivation which is affected by the Assamese ryot.

The cane called *bangala* appears to have been brought from Bengal, either at the time of Captain Welsh's expedition in 1793-94 (as is the tradition in Nowgong), or by European sugar-growers in Kamrup some thirty years ago. In the Mangaldai sub-division, where it is said to be of very recent introduction, and also in North Lakhimpur, this cane is called by the alternative name of *bambo* or *bam*, implying a doubtful connection with Bombay. This foreign variety of cane greatly excels the Assamese in size and juiciness; but as a sugar-producer it generally ranks below the indigenous *mugi*. Like the country cane, it is divided into yellow (*pura*) and red (*teli*); the former, which is much the commoner, is a large soft cane, with stalks averaging eight feet in height and an inch and a half in thickness, while the latter is said in the Mangaldai sub-division to be even larger and more juicy. The Bengal cane is grown chiefly in the southern part of Kamrup, in the Mangaldai sub-division, in Silnagar, and, it is said, in North Lakhimpur. Elsewhere it is cultivated as a garden plant, in tiny patches of *basti* land close by the ryot's dwelling, and is eaten in the raw state after being slightly heated to increase its sweetness, or the juice is used as a syrup in compounding medicinal pills. Though yielding much more juice than country cane, the Bengal kind is apt to break into small pieces in crushing, and thus gives more trash to the mill. A degenerate variety is known by the name of *asamiya puri* in Kamrup, and *keteki puri* in Upper Assam.

The *malaka* or *malaka* cane of Kamrup and Darrung, so called from its resemblance to a kind of reed of the same name, and the *magara* or *megala* of Upper Assam, are a hard and thin variety of the country *mugi*, and, where grown at all, they are planted round the edges of the field, or intermixed with the *mugi*, by chance. This cane, like the *teliya*, is so hard and dry that it may safely be left to protect itself against man and beast.

Two local varieties of cane appear to be peculiar to the Mangaldai sub-division, namely, the *brubeli*, resembling *mugi*, but with shorter intervals between the joints, and the *kamrupi*, a cross between *mugi* and *teliya*. The former is used for medicinal purposes only (chiefly in disorders of the kidneys), and the latter is not intentionally grown at all.

A light loamy soil, with a slight admixture of sand, is the most suitable for sugarcane. The Assamese name for this kind

of soil, *modulia*, denotes at once the waxy consistence of the loam (no meaning wax) and the addition of sand (*hali*). The land must be high-lying (*dam*) and beyond the reach of inundations. Favourite spots are the edges of a marsh, or the banks of rivers, which in an alluvial country tend to raise themselves above the level of the plain. In Nowgong and Kamrup the sloping plain at the foot of the southern hills furnishes good sites for cane, especially in the neighbourhood of streams, and it is in such places that the Bengal cane of Kamrup is chiefly grown. Gravely or sandy soils will not produce sugar-cane, while rich alluvial land gives a luxuriant crop, but with watery juices. The degree of manuring depends entirely upon the ryot's means and inclination. Lands in the vicinity of stations are freely manured with cow-dung and crushed mustard-seed, both before and after planting; on the other hand, a field in the jungle often receives no manure except the ashes of the grass and weeds raked out of the soil and burnt. On the whole, cane-lands are not nearly so well manured in Assam as in Upper India. In Goalpara it is said that the spot usually selected is the site of an old cattle-shed, but this can be true only of sugarcane cultivation on *basti* or homestead land, which forms but a small proportion of the whole.

The best cane is grown either on virgin soil or on old fallow; but land from which a crop of mustard, pulse, or summer rice (*ahu*) has been taken is often preferred as being of less laborious tillage. The exhausting nature of the crop is expressed by the proverbial saying that *athia* (a kind of plantain), *kachia* (rice seedlings), and *gathia* (the knotty crop, i.e., cane) destroy the productive powers of the soil. A second crop of cane, unless ratooned, is never grown in the year next following the first, and though two or three years' fallowing is considered sufficient in the vicinity of stations or large villages, where manure is abundant and cultivation more than ordinarily careful, lands in outlying parts are not considered to have regained their vigour till they have lain six or seven years under a wild growth of grass. Hence such lands are not, as a rule, retained by the cultivator, but are relinquished and retaken at pleasure, whereas the patches near his homestead are usually kept in his own hands, to prevent their usurpation by others.

Waste or fallow land is broken up in October. A good deep hoeing is the best treatment, and if the field be *asthani* (timber land) or *marhani* (stump land), that is to say, a forest clearing now for the first time brought under cultivation, this method is the only one possible; but it is not absolutely necessary in the case of a field reclaimed from reed jungle, while fallow land (*kicari*) can usually be brought under the plough at once. Having thus been turned up, more or less thoroughly, with the hoe or the plough, the land is then left till January or February, when the ryot, having gathered his crop of winter rice, is at liberty to recommence operations; at this time also previously-cropped land (*jahali*) is taken in hand, and ploughing, varied by harrowing, goes on with more or less diligence and frequency until the middle of April. The soil has now been thoroughly worked up, the weeds and grass raked out and burnt, and the clods which have escaped the harrow (*moye*) are broken with the mallet (*dalimari*). The duration and number of these operations vary greatly according to the ryot's inducement or inclination towards careful tillage. The popular estimate of twenty ploughings at least is rather ideal than actual; but the ryot understands perfectly well that the value of his crop depends in a great measure upon the depth and thoroughness of tillage preparatory to planting. Then follows the partitioning of the field (*khandod*) into strips of eight to twelve feet in width (*khand*), separated by drains communicating with the ditch (*khdwai*) which surrounds the field on the outside, and which is dug almost waist-deep. The field is now ready for planting as soon as the first showers fall.

The layers from which sugar-cane is propagated in the Assam Valley consist invariably of the topmost joints, and are hence called *ay* (tops); they are sliced off pretty much at random, but are supposed to measure the length of the forearm with the fist closed, and usually comprise three or four joints. During the interval of two or three months between cane-harvest and planting, the layers are kept in a cool and moist spot in the ryot's homestead, placed in a half-upright position in ground which has been turned up by the hoe, covered with rice-straw or plantain leaves to protect them from the sun, and watered occasionally if the weather be dry. When thus treated, they have already begun to throw out shoots (*gazdli*) before transplanting, but when cane-harvest has been prolonged till late in the year, the interval between the cutting and the planting of the layers is very much abridged, and a regular nursery is dispensed with, the bundles of layers being simply kept in a heap under damp straw until they are wanted; this is called *dhuliya* or "dusty" planting. The day chosen for planting must be preceded by sufficient rain, and if drizzling rain lasts throughout the day, so much the better. It is seldom that the date fixed upon is later than the middle of May, though exceptional circumstances may cause it to be postponed till the end of that month, or even the beginning of June. The layers are placed at distances of about two feet from each other, in trenches three feet apart, which run at right angles to the drains (*khand*) dividing the field, and are thus cut up into lengths of eight to twelve feet. Thus calculated the number of layers required to plant one bigha (120 feet x 120) would be 2,400. A carefully prepared estimate from the Nowgong district shows the number as 2,000 to 3,000. It is less in good land than in poor soil where losses from failure to germinate have to be made good. The rate at which layers are sold is liable, like everything else connected with the cultivation of sugarcane in Assam, to great variations from year to year. The present selling price in the Darrung district is 400 to 500 the

rupees, but it was 600 the rupee a few years ago. After the layers have been planted, a little soil, often mixed with cow-dung, is lightly scattered over them, and they are left to themselves for ten days or a fortnight, until they have struck root.

The field is then weeded, and the soil around the young shoots lightly stirred with the spade (*khandi*) or hoe (*kudali*). The latter process is one of great importance, and ought to be repeated at short intervals on sunny days throughout May and part of June, the earth being thoroughly stirred to the depth of six or eight inches, both around the shoots and also between the lines of canes. Manure also may be applied on these occasions, and one or more weedings are usually given. Later on, the earth from the ridges (*dhia*) between the trenches (*pasi* or *khandi*) is heaped about the roots of the canes to strengthen their hold on the soil, and this process is repeated until the relative positions of trench and ridge are reversed, and the canes now stand on ridges with trenches between. This goes on till the middle of August, at intervals varying according to the leisure and industry of the cultivator; but the popular estimate is that the cane should be hoed once a fortnight until Jeth (ending on the 15th of June), and that the weeding and earthing-up should take place subsequently at least once a month. Sunny days are always chosen, and in the earlier stages the prevalence of sunny weather is especially desired, as the earth about the young shoots cannot be stirred while it is wet without injurious effects.

A prolonged break in the rains while the cane is yet young will occasionally compel the ryot to resort to irrigation to save his crop, but such cases are quite exceptional, and seem to be unknown in Upper Assam.

Work in the cane-field is usually at a standstill for about a month from the middle of August. During this time the juice of the cane is sweetening, and the ryot is said to feel a superstitious aversion from entering the field, lest the jackal should follow him. A final weeding and earthing-up are administered towards the end of September or the beginning of October, the canes being at the same time tied together in clusters as they grow, by means of the leaves stripped off the lower part of the stalks, and bamboo props are sometimes added by way of support where the crop is exceptionally tall and valuable. The number of canes springing from a single layer may vary from three to ten, but is usually either four or five, and where more numerous, the canes fall off in size. The person who undertakes the tying-up must be completely clothed, with his hands protected by a covering of cloth, and his feet by sandals of leather or the bark of the betel-plum. It is a laborious process, and is often omitted. Indeed, the whole of the foregoing description must be taken as true only of the more careful style of cultivation practised in the immediate vicinity of villages, while in forest clearings, or patches in the midst of reed jungle, the cane is left pretty much to shift for itself.

Nothing more has to be done now but to fence in the field securely with slips of bamboo intertangled, so as to form a continuous paling about three feet high, and strong enough to cost some trouble in pulling to pieces. Though of no avail against bears or wild elephants, this does save the crop, to some extent, from wild pigs, and from a still more mischievous enemy, the jackal, who, nevertheless, often contrives to find his way in, and eat a large space clear in the centre of the field. The roots of the growing cane, especially if too freely manured, are liable to be attacked by white-ants (*ni pok*), and, in uncovering them to rid them of this pest, injury is sometimes inflicted upon the plant. A rainy October, followed by a dry November and December, causes the top joints to wither and die. Apart from these calamities, however, sugarcane in the Assam Valley does not appear to be liable to any special disease. It does not suffer much from inundation, as the sites selected usually lie beyond the reach of any ordinary flood, while drought is a contingency that hardly comes into the cultivator's reckoning.

A small proportion of the annual cane crop is ratooned, i.e., grown from the roots of the last year's cane, instead of being propagated by layers. The stripped leaves of the previous crop are left lying on the field till April, when they are burnt, and a month later, when the young shoots begin to appear, a hoeing may be administered and some manure added. Such a crop is called *murka*, or stump cane; it receives little attention from the cultivator, ripens early, and yields only about half as much coarse sugar as an equal area of cane cultivated in the ordinary way. A peculiarity of *teliya* cane, and one of its recommendations to the Assamese ryot, is that it can be ratooned twice.

With the exception of *murka* cane, which is cut early in January, cane harvest does not begin until the winter rice has been reaped and stored. The date is somewhat earlier in Goalpara and Kamrup than in the upper districts, but generally it may be said that the festival of the *Majh Bihu*, or harvest-home of the principal food-crop of the year, corresponding in date more or less exactly to the 15th of January, is celebrated before the cultivator troubles himself with the labours of the cane-press. The operations of cutting, crushing and boiling are carried on simultaneously from this date until the end of March, or even the first few days of April. The canes are cut off close to the root by a single stroke of the Assamese *dao* or bill-hook, the tops are lopped off for layers, and the stalks, stripped of their leaves, are bound in bundles (*muha*) weighing about half-a-mund, and carried to the mill. Where the crop is *pura*, or good, *mugi* cane, a small proportion is usually reserved for eating in the raw state, and is worth one or two pie. per stalk in the village markets, while in the station bazaar a single stalk is cut up into several pieces, each of which is worth a pie. Thus estimated, the value of a field of sugarcane depends on the number of stalks; and these vary greatly, according to the cultivator's ability to plant the field properly and to protect the growing crop. If we assume an average of one cane to every two square feet, the value of the canes on

one rood of land, if sold for eating raw, would be about Rs. 50; but this is quite an imaginary case. The great bulk of the cane grown in the Assam Valley is destined for the mill. Unless of extraordinary length, the canes are not divided before crushing (in Goalpara, however, they are said to be cut up into lengths of 2½ feet), but are passed through entire; the average length of *teliya* cane, stripped, and topped is less than four feet, of *mugi* nearly five feet, and of Bengal *pura* about six feet. The cultivator is well aware of the importance of protecting the juice, while in the cane, from exposure to the air, and therefore he crushes his cane undivided, and only cuts it by parcels as he wants it for the mill, which is always set up in the immediate vicinity of the cane-field.

The sugar mill (called *kharaka* in Goalpara, and *adi* in Upper Assam) is a rude but tolerably effective machine, and a quicker and less dangerous worker than the heavy beam-and-pestle arrangement of Upper India. It consists of two vertical rollers (*dhim*) placed in juxtaposition, with their lower ends resting in a flat trough (*dhoral*) scooped in a solid and heavy block of wood (*toljoli*) resting on the ground, while their upper ends pass through a rectangular space cut in a horizontal beam above (*borjoli*) supported by uprights (*kol khuta*) set through the lower block into the ground. The rollers are held in their places by vertical clamps (*ghara*), which grip them at the upper and lower ends, and are driven home by wedges (*khal*). The portions of the rollers which project above the upper beam (*borjoli*) are grooved so as to work into each other on the principle of an endless screw. The driving power is a horizontal beam (*khatari*), applied to the head of the taller or "male" roller (*mata dhim*), upon which the shorter or "female" roller (*matki dhim*) revolves in the contrary direction. The "male" roller is usually, if not invariably, that on the right hand as one faces the mill and the direction of progress is from left to right, that is to say, the men at work walk round with the left shoulder inwards. Buffaloes are seldom yoked to an Assamese sugar-mill, and bullocks never. The whole machine is made entirely of wood, without a nail or a piece of iron in its composition, and its value varies according to the kind of wood used. A mill can be built of tamarind-wood for eight rupees, but in *jam* wood (*khajania jambulana*) it will cost twelve, and if *nehor* (*Mesua ferrea*) is used, as much as fifteen rupees.

All being ready for crushing, the first thing the cultivator does is to bind two of the finest cane-stalks along the beam of the mill, as an offering to Viswakarma, the god of artificers. The canes are then passed through the mill in batches (*ana* or *kan*) of six or eight at a time, the juice falling into the trough, and thence through a hole on to a sloping wooden tray, which transmits it by a lip of plantain leaf to the earthen vessel placed to receive it in a pit dug below. In some places the tray (*ramkhara*) is circular in shape, with a raised wooden edge and a funnel-shaped escape-moment for the juice, but usually a simple slab of wood, slightly concave, is considered sufficient. The working of the mill is accompanied by a loud and strident noise which is welcomed by the ryot as a sign that the rollers are biting well, and is, moreover, a cheerful and useful accompaniment while the work is carried on by night, as is the practice towards the end of the season, when the heat of the day would be injurious alike to the men and the cane-juice. Each handful of cane is passed through the mill three or four times, until they begin to yield mere foam, when they are thrown aside, and a fresh batch takes their place. *Mugi* and *pura* cane squirt out their juice plentifully on the first compression, and give less afterwards, while the harder and tougher *teliya* passes through almost dry, and only begins to yield juice to the second squeeze. At the third and fourth crushings, the flattened canes are usually twisted into a rope, so as to present a bulkier body for compression. A boy sitting in front of the mill draws them out as they pass through the rollers, and hands them back to the man who sits behind and feeds the mill. Four or five men drive the machine, resting their hands on the beam, and pushing against it with the chest and shoulders. The force required to put the mill in motion was ascertained in one experiment made by Mr. R. T. Greer, sub-divisional officer of Golaghat, to be 5 to 6 lbs. without cane, and 40 lbs. with *mugi* cane between the rollers, but 60 lbs. with *teliya*. The rate of progress in crushing is about two

* Messrs. Mylne and Thomson claim for their Beha mill the power of crushing twice as much cane in a given time as the common *kolhu* of Behar and the N.-W. P. Their calculations (which are supported by independent experimental evidence) make the average output of the *kolhu* about 100 lbs. per hour. The Assamese mill works at least half as rapidly again.

† The following are the dimensions of a sugar-mill measured in the Majhuli, and may be taken as fairly representative of the machine commonly used in Assam:—

| | Length. Ft. In. | Breadth. Ft. In. | Thickness or depth Inches. |
|---|--------------------|---------------------|-------------------------------|
| <i>Toljoli</i> ... | 4 0 | 1 2 | 3½ |
| Trough scooped in <i>toljoli</i> ... | 2 0 | 0 7½ | 2½ |
| <i>Borjoli</i> ... | 6 6 | 1 2½ | 6 |
| Rectangular space in <i>borjoli</i> ... | 1 11 | 0 9 | 6 |
| Total length of rollers ... | 3 6 | ... | ... |
| Circumference ... | 2 4½ | ... | ... |
| Length of grooved part ... | 1 1 | ... | ... |
| Breadth of grooves ... | 0 2½ | ... | ... |
| Depth of ... | 0 2 | ... | ... |
| Height of uprights ... | 2 6 | ... | ... |
| Circumference ... | 2 4 | ... | ... |

The length of each arm of the beam was about nine feet. The smooth or ungrooved portion of the rollers was thus 2 feet 5 inches in length, but from this must be deducted the spaces covered by the depth of the trough below and the thickness of the *borjoli* above, i.e., 2½ inches and 6 inches; thus, 2 feet 5 inches—8½ inches=1 foot 8½ inches, the length available for crushing.

maunds (165 lbs.) per hour. A good deal of trash and impurity—earth from the imperfectly-cleaned canes, fragments of the stalk, dust carried by wind, &c., enters the earthen pot along with the juice; in fact after a couple of hours' work, mud can be plentifully scraped off the plain-leaf lip of the tray, but the ryots seldom trouble themselves to clean it. When the pot is full it is changed for another. As the work proceeds the wedges holding the clamps have usually to be driven home from time to time to counteract the tendency of rollers to work asunder.

The juice is thrown into a boat (*ndor*) scooped out of a log. This stands at the edge of the boiling-house, a few yards removed from the mill, and sometimes contains leaves of the wild fig tree (*damaru*), which are supposed to be useful in keeping the juice sweet. When some twelve or fifteen gallons have been collected, the boiling begins. The whole apparatus for this purpose is worth about two rupees, and consists of four earthen cauldrons (*chal*), two ladles (*lakhols*) made of half-gourd attached to the end of a stick, one of which is usually perforated like a colander, and a sieve or strainer (*jaki* or *chalan*) of plaited cane with a long handle. The furnace is excavated in the ground, and has four circular openings to receive the cauldrons; the first of these is set some three feet back from the furnace mouth, the second about as far behind the former, while the last two, which are placed side by side at much the same distance in the rear, lie almost beyond the reach of the fire, and are used merely as feeders in which the juice is heated before being transferred to the first or second cauldron for boiling. The cauldrons are invariably made of potter's clay, and in shape are almost exact hemispheres, with a diameter of eighteen to twenty-one inches; the first two, being somewhat larger and of superior quality, usually cost as much as seven or eight annas each, and must be procured from certain potteries where the clay is exceptionally good; Kokilamukh, for instance, enjoys this reputation in Upper Assam. The two feeders can be purchased for about four annas a-piece. Before placing the cauldrons on the fire, their bottoms are smeared with clay tempered with cane juice, while a charm* is repeated to keep them sound and whole: in this way they can be made to last for one or two seasons, and though commonly cracked in all directions, the ryot continues to use them until the bottom falls out, when the fire is withdrawn and the spilt juice carefully scooped up from the floor of the furnace, and strained through a cloth into the new cauldron which is always held in reserve on such occasions, the whole apparatus being at the same time protected against the recurrence of such a malicious mischance by the sprinkling of water over which charms have been muttered against the evil eye.

The fuel consists of reeds (*khagari* or *ekra*), supplemented by the crushed canestalks (*jaban*) as the boiling proceeds. A man or boy feeds the fire, while two men mind the cauldrons, skimming the feeders with the sieve, and lifting the juice in the boilers with the ladle so as to prevent it from boiling over, while they replenish the second cauldron from the feeders, and thence transfer the heated juice to the first cauldron immediately over the fire. This latter operation is usually performed by the man who is entrusted with the duty of determining the exact point at which the juice has been boiled enough: he is always an experienced person, and must be fed well and treated with deference. Lime-water is said to be occasionally administered as the boiling goes on, but this is mentioned in the district of Nowgong alone, and is probably quite an exceptional precaution. In the latter stages of the boiling, care is taken by frequent interchanges of juice to keep the two boiling-cauldrons as nearly as possible at the same temperature. These stages are three in number, and are vulgarly known by the names of *o-phulla*, *babori-phulla*, and *temi-mulia*, implying that the ebullient masses of liquor in the first stage are as large as the fruit of the *O* tree (*Dillenia indica*) that is, about three inches in diameter; in the second stage they are more frequent, and shrink to the size of the flower of the *babori* (an edible species of the *Compositae*) in size about equal to the marigold; while in the final stage they present a hollow in the centre, and are thus compared to the little box (*temi*) in which the Assamese peasant carries his stock of lime for consumption with betel-nut. On the appearance of this last sign, the boiling cauldrons are rapidly emptied with the ladle, and replenished again from the feeders without delay, while the fire, which had been slackened at the *o-phulla* stage, is again quickened by feeding it first with two reeds dipped in the fresh molasses, as an offering to the god Agni. The duration of operations depends of course upon the quantity of juice, but the ryot always reckons upon converting his *pal* of cane into sugar in a single day or night that is, with eight to twelve hours' work. Reduced to an average rate, this means that about thirty gallons of juice can be boiled in five or six hours. When the last instalment of juice has been disposed of, the boiling cauldrons are rapidly rinsed with a little warm juice and lifted off the fire.

The liquid stuff ladled out of the cauldrons is received in a wooden vessel (*gholani*) about six feet long, made and shaped in the same manner as the ordinary Assamese dug-out, but with one end out square; where it is stirred with a Y-shaped instrument consisting of a triangle of bent bamboo fastened to the end of a stick (*Adhar* or *ghotanimari*). As the stirring continues, the liquid loses its dark brown colour, and assumes the hue and con-

sistency of yellow mud. The process lasts half-an-hour. The *gur*, or compost, is then removed from the *gholani* with the hand or a broad slip of bamboo, and put into earthen pots. This concludes the proceedings. The manufacture of refined sugar is an art which has yet to be introduced into the valley of the Brahmaputra.

The word *pal* is used to denote the quantity of cane which is crushed and converted into sugar at a single spell of work, whether by day or by night. The quantity of cane in a *pal* depends a good deal upon whether the cultivator is or is not working against time. It usually consists of twenty bundles, which may be roughly assumed to weigh 10 maunds, or about 800 lbs., but twice as much can be disposed of towards the end of the season, when work begins after the evening meal (9 or 10 p.m.) and continues without intermission through the night and into the forenoon of the following day. The quantity of cane got through on such occasions is commonly reckoned as the produce of one *cottah* (one-fifth of a *bigha*, or 320 square yards). When working by day, the cane is cut and brought to the mill as it is wanted, but for night work it must be cut and stacked before dark. Boiling begins when half the cane has been crushed, and goes on for several hours after all other operations have been concluded. The usual custom is to boil the juice yielded by one *pal* of cane in two instalments as nearly equal as can be guessed, neither of which, however, need fully test the capacity of the boiling apparatus, which is capable of dealing with twenty gallons at once, if the ryot has so much to put into it. The relation between the weight and the volume of the juice has been determined by a series of experiments to be about 11 lbs.* avoirdupois to a gallon: as compared with water, the weight, volume for volume at a temperature of 75° F., was found in one experiment to be as 74 to 67.

It will probably have been perceived from the foregoing description that the manufacture of sugar in the Assam Valley is a purely domestic industry. The ryot has no relations whatever with any manufacturer or money-lender. He grows his cane entirely on his own account, and converts it into sugar by the help of his neighbours, who work for him on the understanding that he will work for them when their turn comes. This system of mutual assistance relieves the ryot of a good deal of labour, and of almost all expenses; nevertheless, the cultivation of sugar-cane is regarded as a most laborious undertaking, to be attempted only, as the proverb says, by one who has a large family at his back:—

Soy po barah nati,
Tehe koriba kuhlyar khetl;

with six sons and twelve grandsons a man may cultivate sugar-cane.

The area planted by a single family rarely exceeds half a *bigha* (800 square yards), and is often much less; and whenever a large field of cane is met with, it will be found to consist of several such plots belonging to different families, who have cultivated the whole, as they will crush and manufacture its produce, by their united labour applied to each plot in turn.

In reference to an industry conducted on such conditions as these, the term "cost of production" is apt to be misleading; and, in fact, on making the calculation at the ordinary rates of hired labour, the expenditure may easily prove to be greater than the value of the article obtained. It is difficult to form an estimate of the cost of cultivation and manufacture that can be relied on with any degree of confidence, but the following statement, compiled from returns furnished by district officers, may be regarded as not very far from the truth:—

Cost of cultivating, crushing, &c., the cane on half a *bigha* of land (800 square yards).

| Cultivation. | | Rs. | As. |
|-------------------------------------|-----|-----|-----|
| Hoeing in October | ... | 0 | 8 |
| Ploughing and harrowing (8 times) | ... | 3 | 0 |

| (fuel) | ... | 2 | 4 |
| (one-half value of vessels) | ... | 0 | 12 |
| | | 12 | 0 |
| Total | ... | 23 | 12 |

The quantity of sugar manufactured from a given weight of cane by the rude processes known to the Assamese ryot is considerably less than the cultivator obtains in other parts of India, and will not bear comparison at all with the produce of a West Indian factory. A large number of experiments have been made by various officers with a view to ascertain the actual proportions, in weight, of the

* The Saidpet experiments, alluded to further on, give an average of 9½ lbs. per gallon.

* A charu commonly used in the Nowgong district runs in this way:—
"Sat patol mēti, Anat kumārē anile kati; Khochi guli dile chakāt,
Charu hot Brahmar pēlot. Hari Har dāk. Phuta, phata, khakā,
khāpori, bali jāle, sakar kona, jora lagi thak."

That is to say, "Anat the potter cut and brought the earth of the seven worlds, kneaded and wet it, and put it on the wheel; it became a cauldron under Brahma's turning. Call on Hari (Vishnu) and Har (Shiva). Breakage and cleavage, chip and potsherd, sand-leak and crevice, be joined and whole."

juice and the compost obtained from a given weight of cane. Where made by European or educated native officers, these experiments may generally be regarded as accurate, or as liable to error chiefly on account of the occasional reluctance of the ryots to assist heartily in operations which they secretly regarded as the preliminaries of new taxation. A series of experiments in a rougher fashion and on a larger scale have been conducted by subordinate revenue officers (*mauzadars*). Here the recorded weights represent the results arrived at by multiplying the average weight of a few bundles of cane, or vessels full of juice or compost, by the number of bundles crushed, and the number of vessels filled. Covering, however, comparatively so large an area, these experiments may be regarded as giving general results that are fairly trustworthy, especially when we consider their remarkable correspondence with the results obtained by superior officers. The two classes of experiments have been tabulated separately, and in detail, at the end of this Note (Appendices A and B). Collating them by districts, we find results as follow :—

Experiments by District Officers.

| Districts. | Number of experiments. | Weight of cane crushed. | Weight of juice. | Weight of gur. | Per 100 lbs. cane. | |
|---------------------|------------------------|-------------------------|------------------|----------------|--------------------|-----------|
| | | lbs. | lbs. | lbs. | lbs. juice. | lbs. gur. |
| General results ... | 5 | 10,613 | 4,969 | 707 | 40.7 | 6.0 |
| Lakhimpur ... | 7 | 7,671 | 3,268 | 589 | 42.6 | 7.4 |
| Sibsagar ... | 8 | 13,567 | 5,722 | 1,118 | 42.2 | 8.2 |
| Darrang ... | 11 | 7,218 | 2,781 | 367 | 38.7 | 5.1 |
| Kamrup ... | 3 | 2,887 | 1,205 | 223 | 42.5 | 7.8 |
| Golpara ... | 32 | 41,900 | 17,935 | 2,081 | 42.8 | 7.1 |

Experiments by Mauzadars.

| | | | | | | |
|---------------------|----|--------|--------|-------|------|-----|
| Kamrup ... | 3 | 3,624 | 1,420 | 232 | 39.2 | 6.4 |
| Darrang ... | 9 | 1,201 | 8,187 | 1,442 | 44.7 | 7.4 |
| Nowgong ... | 2 | 2,592 | 1,826 | 284 | 61 | 8.8 |
| Sibsagar ... | 15 | 53,034 | 20,483 | 3,781 | 50 | 7 |
| Lakhimpur ... | 1 | 1,028 | 411 | 82 | 40 | 8 |
| General results ... | 30 | 78,479 | 37,777 | 5,721 | 48.1 | 7.8 |

We may reasonably conclude from these figures that the ordinary cane-crop of the Assam Valley cannot be counted on to yield more than 43 per cent of its weight in juice, and 7 per cent of its weight in coarse sugar. For an average struck upon all kinds of cane cultivated under all circumstances, even these figures are probably too high. Much better results may be obtained where special care has been bestowed upon the crop; the list of experiments by district officers at the end of the note shows that in several instances 50 and even 60 per cent of juice, and 10 to 13 per cent of gur has been got from a given weight of cane; but these are exceptional cases, and do not represent the sugar-yielding capabilities of the common cane of the country.

The weight of cane grown on a given area of land varies much more than the proportion between a given weight of cane and the weight of juice or gur obtainable from it. The species of the cane makes a considerable difference; *pura*, for instance, is a much heavier crop than *teli*. Speaking generally, a well-cultivated field will yield to the mill about one pound of cane to every square foot, while a field carelessly cultivated, or insufficiently planted, or exposed to the depredations of animals, will hardly give one pound to every three square feet of its area: thus the limits vary from six to nineteen tons per acre; while an arithmetical mean, which is probably somewhat in excess of the actual average, may be deduced from the following statement, compiled out of the details given in the appendices :—

Experiments by District Officers (24 in number).

| Districts. | Area cut (square feet.) | Weight of cane. lbs. | lbs. per acre |
|---------------------|-------------------------|----------------------|---------------|
| Golpara ... | 10,890 | 8,722 | 34,888 |
| Kamrup ... | 14,536 | 6,067 | 18,180 |
| Darrang ... | 18,577 | 13,567 | 31,814 |
| Sibsagar ... | 12,876 | 7,218 | 22,419 |
| Lakhimpur ... | 3,180 | 1,769 | 22,695 |
| General results ... | 60,059 | 37,343 | 27,083 |

Experiments by Mauzadars (30 in number).

| Districts. | Area cut (square feet) | Weight of cane. lbs. | lbs. per acre. |
|---------------------|------------------------|----------------------|----------------|
| Kamrup ... | 10,332 | 4,396 | 18,417 |
| Darrang ... | 29,916 | 18,201 | 28,500 |
| Nowgong ... | 4,284 | 2,592 | 26,358 |
| Sibsagar ... | 78,920 | 53,703 | 29,270 |
| Lakhimpur ... | 1,440 | 1,028 | 31,097 |
| General results ... | 125,892 | 78,920 | 27,429 |

These figures, though without any pretension to absolute accuracy, may be accepted as representing the results of measurements and weighments made with as much care as would be taken in a wholesale commercial transaction. In using them for the purpose of educing general averages, it is necessary to remember that the most promising plots stand the best chance of being selected for

experiment, that fields in the jungle must be rated far below those in the vicinity of villages, and that while the great majority of the experiments were made with *mugi* cane, it is the less productive *teliya* which the district reports would lead us to regard as the predominant species. Bearing these facts in mind, we may perhaps conclude that the average Assamese cane-field bears 10 to 11 tons per acre; and such a weight of cane will yield about 1,400 lbs. of gur. Compared with other parts of India, these results are poor. In the North-Western Provinces the average yield per acre, irrigated and unirrigated, taking all the districts together, is estimated at 2,300 lbs. of gur,† and the gur of Upper India is better dried and more durable than that of Assam. Part of this superiority in yield of sugar is due to the greater quantity of juice expressed, for cane in the North-Western Provinces gives one-half of its weight in juice. If we look to Madras, it appears that the common country mill of the Bellary district, built on much the same principle as the Assam mill, but costing Rs. 72 for the rollers alone, can extract 66 lbs. of juice out of 100 lbs. of cane, and this will yield 12 lbs. of sugar,‡ or double as much as could be got from the same weight of cane in the Assam Valley. The fault lies less in the Assamese mill than in the cane; for the Bihis mill extracts 67 per cent of juice from Madras cane, while the best experiment with it in the Assam valley has not given more than 56 per cent. In Behar the average produce of gur per acre is estimated at the very high figure of 40 maunds, or 3,300 lbs.; in lower Bengal (the Rajshahyee and Burdwan districts) at 2,500 to 1,800 lbs.; § lastly, in the Beilin cane tract in British Burmah, the outturn of an acre well cultivated is estimated at 3,500 lbs. of gur.¶

We are now able to complete our calculation of the ryot's profits on sugar-cane. The cost of growing and converting into coarse sugar the cane on half a bigha of land (800 square yards) was estimated at Rs. 23.12. The produce will be some 4,000 lbs. of cane, which may be expected to yield about 240 lbs. of the compost called *gur*. The ryot will probably keep the greater part of this for domestic consumption; but on the supposition that he disposes of the whole of it by retail sale in the petty markets, it will fetch about 2½ anas per seer, or some 19 rupees altogether, thus falling to cover the cost of cultivation and manufacture.¶ The mode of sale is in small earthen pots containing about 2 lbs. each, and worth from two to three annas, or even as much as six annas in a dear year; or else in large earthen vessels (*kalis* or *kalah*) holding some 20 lbs., and priced according to their weight; or he may sell by the maund, at the rate of four to five rupees. The conditions of production, however, are such that nothing like a fixed proportion exists between supply and demand. The market gets only the surplus from domestic needs, and the price rises and falls from year to year according as this happens to be little or much. In 1879-80, in the Nowgong district, a *teli*, or small earthen jar, containing about two seers of gur, sold for 8 to 10 annas, or at the rate of about 10 rupees per maund; the present year, on the other hand, is one of abundance, and gur was selling in April at Rs. 2½ per maund in Kamrup and Darrang, while the price throughout last year in the vicinity of Dibrugarh ranged from Rs. 8 to Rs. 9 per maund. Assamese gur is never sold in the large balls or masses of hard compost which are so familiar in the bazaars of Upper India. In the winter it barely attains a solid consistency, and shows a slight tendency to granular crystallisation, but as the weather grows hotter it liquifies, and if not speedily consumed often becomes sour and useless.

* NOTE.—It is hardly necessary to repeat that a single field of one acre probably does not exist in the valley of the Brahmaputra.

Some additional statistics may here be quoted. Five experiments made last year in Sibagar, on an area of 1.13 acres altogether, gave an average outturn of 1,517 lbs. of gur per acre. The average assumed in the text is perhaps corroborated in some degree by the rough estimates of the ryot. In the southern part of the Kamrup district 20 to 25 *kalis* are estimated as a fair outturn for a bigha of land. The *kalis* contains about 20 lbs. of gur, so that the outturn of gur per acre would be 1,200 to 1,500 lbs. Another estimate is 8 *kalis* per *cottah*, or 1,800 lbs. per acre, as the produce of a good field. In some villages where cane-crushing was going on, I measured up the area of cane cut for a single *pal*, and weighed the gur obtained, with results as follows :—

| Square foot. | lbs. gur. | lbs. per acre. |
|--------------|-----------|----------------|
| 3,875 ... | 62 | 796 |
| 3,038 ... | 52 | 776 |
| 3,177 ... | 56 | 769 |
| 7,200 ... | 131 | 807 |
| 972 ... | 47 | 2,100 |
| 1,740 ... | 74 | 1,860 |

These very poor results obtained by ryots when working by themselves show that the estimate in the text is not too low.

† Field and garden crops of the North Western Provinces and Oudh, Roorkee, 1882.

‡ Salapet Experimental Farm Report for 1881-82.

§ These figures are taken from papers published by Messrs. Thomson and Mylne.

¶ Quoted from a Note by Mr. D. M. Smeaton, Director of Agriculture, dated the 9th October 1882.—These figures, however, seem small in comparison with some statistics of cane cultivation in Australia. I find it stated in the *Brisbane Courier* that the outturn per acre on one Queensland plantation is estimated at 37 to 40 tons of cane, and one ton of cane gives 150 gallons (about 1,500 lbs.) of juice.

¶ In confirmation of this estimate, which I believe rather underrated the loss which would follow cultivation by *hired labour*, I may mention that a European engaged in farming near Bishwanath in the Durrung district showed me a crop of the *pura* cane which had already cost him so much that he doubted whether it would be worth his while to cut and crush it. It will be observed, moreover, that one of the ryots quoted in the note above got only 13½ lbs. of gur from his half bigha of cane.

The area under cane in the valley of the Brahmaputra in 1882-83 is stated to be as follows:—

| | Acres. |
|-----------|--------------|
| Goalpara | 425 |
| Kamrup | 4,381 |
| Darrung | 2,219 |
| Nowgong | 4,283 |
| Sibsagar | 3,630 |
| Lakhimpur | 713 |
| | <hr/> 15,656 |

These figures must be regarded as only an approximation to facts. There is reason to believe that for Goalpara (where we have to depend on the zemindars for our statistics), they fall short of the truth, while in other districts some jungle cultivation may have escaped record. Again, the area is subject everywhere to great fluctuations from year to year. A dear season stimulates production while a cheap one discourages it; and thus cultivation is liable to contract and expand in alternate periods. Thus, in Nowgong the high price of *gur* in 1879-80 was followed next year by an increase of nearly 70 per cent in cultivation, while the low price of 1881-82 induced a decrease of 30 per cent in the year following. Taking the total area under sugarcane in the Assam valley to be 16,000 acres in round numbers, the average outturn as 1,400 lbs. of *gur* per acre, and the price as Rs. 4-8 per maund of 82 2/7 lbs., the whole weight of sugar produced in a year would be 10,000 tons, valued at Rs. 12,25,000.

The whole of this is locally consumed, no portion being exported either to Bengal or to the frontier tribes. It is not, in fact, sufficient by itself for the wants of the country. The import from Bengal during the last three years has been as follows:—

| | 1880-81. | 1881-82. | 1882-83. |
|-----------|--------------|--------------|--------------|
| | Maunds. | Maunds. | Maunds. |
| Refined | 13,217 | 11,564 | 10,974 |
| Unrefined | 39,473 | 28,849 | 34,980 |
| Total | <hr/> 52,690 | <hr/> 40,413 | <hr/> 45,954 |

Refined sugar is consumed almost exclusively by Europeans, well-to-do Bengalees, and Marwari traders, or is used at festivals in the great *Shattras*. If unrefined sugar alone be taken into consideration, we find that the average annual import during the last three years has been 2,835,426 lbs., and, the local production of sugar being 10,000 tons, the sum of these two quantities, when divided by the population of the Assam valley (2,225,271), gives a yearly consumption of 11 mds. per head. This calculation tends to show that the average outturn of sugar per acre has not been under-estimated. In the Punjab and the North-Western Provinces the estimate of the consumption of sugar made for the Famine Commission in 1879 was 30 lbs. per head of the population, and when we remember how largely the Brahmaputra valley is peopled by races (Meoh, Kachari, Mikir, Lalung, &c.) to whom the use of sugar is unfamiliar, besides the utter absence of large cities with their wealthy classes, it is difficult to believe that the average consumption in this part of Assam can exceed one-third of the figure estimated in Upper India.

The first condition necessary to any improvement of the cultivation of sugarcane in the Brahmaputra valley is a wider market. There is no present demand beyond domestic wants, if we except two small ventures in the Sibesar and Lakhimpur districts, which prove, in their limited way, that the production of sugarcane can be stimulated without difficulty. These are two distilleries established by enterprising Europeans near Golaghat and Dibrugarh, where the *gur* of the country is converted into rum for consumption by tea-garden coolies. Situated in the centre of thickly-peopled tracts, these factories have stimulated the production of sugarcane considerably within the limited area on which they draw for their supplies. The Dibrugarh factory uses Bengal *gur* largely, while that of Golaghat depends entirely on local production. When the latter was first started in 1879, the proprietor found some difficulty in procuring *gur* at all, but now he draws upon the cane crops within a radius of five miles, and cultivation in the neighbourhood has increased about 28 per cent. But neither the one concern nor the other is on a sufficiently large scale to affect seriously the general cultivation of cane, or to test the remunerativeness of such an enterprise if conducted with a larger capital.

These enterprises are by no means the first of their kind. A similar experiment was tried in the preceding generation by a Mr. Herriot in Gauhati, and a Mr. Wood at Dobapara, in the Goalpara district, and ruins of old rum or sugar factories existed, or still exist, near Jorhat and at Numaliguri (now a tea-garden) in the district of Nowgong. The end of all these speculations, whether from the dearth of labour in the Assam valley, or as has been alleged in Gauhati, from mismanagement of the concern, was a failure so complete that no record of them can now be obtained, and we do not know how far they depended on the produce of the country, or sought to supplement it by importations of *gur* from Bengal. It is probable that they all started in the hope of finding a new field for sugarcane in Assam, and the efforts made by Mr. Herriot to introduce a better kind of cane were so far successful that the best cane of the present day in Kamrup and Darrung traces its origin to them. The native cane being so small, hard, and dry, one obvious means of improvement is the introduction of a better stock from Bengal or elsewhere; and experience has proved that the soil and climate are sufficiently congenial; but the cultivator will take no steps in this direction by himself, and in the large areas of thinly-settled country the native canes will always be preferred, as needing less protection from wild animals, and entailing a smaller loss in their destruction where protection proves insufficient. The ravages of wild beasts

are no trifling obstacle to the development of cane cultivation in this part of India.

It has already been stated that refined sugar is nowhere manufactured in the Assam valley. Even in the manufacture of *gur*, however, no one who has witnessed the rude processes employed by the ryot can doubt that very great room remains for improvement. Reasons have already been given for believing that the country mill works more rapidly than the *kolkas* of Upper India, and perhaps it may, therefore, be somewhat less effective as a crusher; but, on the whole, it seems probable that the smaller proportion of juice obtained in these parts (42 per cent. against 50) must be attributed mainly to the inferiority of the cane. Recent experiments, however, with Mr. Cantwell's modified form of the Bihar mill* show that Assamese cane can be made to yield as much as 50 per cent of its weight in juice. It is in the boiling that the greatest loss occurs, 100 lbs. of cane yielding only 5 or 6 lbs. of *gur*, against 15 to 18 lbs. in the North-Western Provinces and 12 lbs. in Madras. This difference, while probably arising in part from the poorer quality of the juice, is also due in great measure to carelessness in manufacture. In the vast majority of cases, no preventives of acidification are used in any stage of the process, and the boiling is often conducted by guess work.

The valley of the Brahmaputra is a country of peasant proprietors, in comfortable circumstances indeed, but without intelligence, enterprise, or capital, and any improvement, whether by the introduction of better kinds of cane or of a better mill, or by greater care in the manufacture of sugar, must be looked for from without.

Land fitted for sugarcane can be leased from Government at the yearly rent of 8 annas a *bigha*, or Rs. 1-11 per acre (including assessment to local rate), and there is the widest possible choice of sites. It is, however, more than doubtful whether cane-growing by hired labour could be made to pay: on the other hand, the central factory system, which has proved so successful in the West Indies and in Australia, can scarcely be introduced in the present defective state of communications and means of transport in the Assam valley. Where the commonest vehicle for loads is a bamboo carried on men's shoulders, there is obviously some difficulty in transporting the produce of an acre of sugarcane to a mill situated at a greater distance than a few yards.

B.—THE SURMA VALLEY.

(Sylhet and Cachar.)

Sugarcane is cultivated in the Surma Valley in much the same fashion as in the valley of the Brahmaputra, but the local names of the common kinds of cane are different. In Sylhet, besides the so-called *Bombay* cane we find the *dhali*, or white, and the *surang*, or red, cane; in Cachar the *Bombay* cane is highly esteemed as the largest and juiciest and the best sugar-producer, and is sometimes grown as a garden product and eaten in the raw state, while the *langli* cane appears to correspond to the *mugi*, and the *shamsheri* or *kamrangi* to the *teli* of the Assam valley. Both districts possess also a small hard species, called *khagari*, or red cane, which may be compared to the *malaha* of the Assam valley, and in Cachar this and the other inferior sorts are said to be most in favour, as requiring less care and being less liable to disease or the attacks of grubs and wild animals. The site chosen is high land in the vicinity of a village if possible (*chara*), or, failing room there, on the bank of a river. Oil-cake (*parkai*) is used as manure a couple of months after planting, if the cultivator happens to have had a mustard crop of his own, and in Sylhet it is even bought for the purpose.

The processes of manufacture are practically the same as those which have been described at such length as prevailing in the valley of the Brahmaputra. The mill, here called *kamrangi* or *ghani*, is sometimes driven by bullocks, and the Cachar ryot is said to cut his cane-stalks into pieces twenty inches long before crushing; in this district also iron caddrons (*kirchi*) are occasionally employed. In some parts of Sylhet the cultivator boils the juice imperfectly, and sells the liquid product (or so much of it as he does not want) to men of the *Lorait* caste, who boil it down into solid compost (*bandha gur*). The liquid or *lali gur* is worth about Rs. 2, and the hardened compost some Rs. 4 to Rs. 5 per maund. Refined sugar is never made.

The cultivator of sugarcane in the Surma valley is independent of the money-lender, unless he is beginning for the first time, and has not ready money to buy cane-cuttings. In that case he takes an advance, repayable with interest when the crop is harvested. The rate at which cane-tops sell in Cachar is stated as 200 the rupee, but this seems exceptionally high. In Sylhet, again, the ryot is said to borrow money to buy oilcake (*khaki*) for manure.

There is no system of village records in the Surma valley, and the estimates of the area under sugarcane must therefore be regarded as conjectural. The method employed in Cachar was to require returns through the officers in charge of police-stations, from the village police-men of their circles; these latter furnished lists of the sugarcane fields within their beat, giving the length and breadth of each in "reeds" of 24 feet, and the station officers worked out the circle areas and sent them into head-quarters. This gave a total of 786 acres, but it was believed that their apprehensions of new taxation had induced the people to understate the facts, and on a comparison with the results obtained by actually measuring up the area under cane in three mauzas of each tahsil, the total extent of sugarcane cultivation in the district has been estimated at 900 acres. For Sylhet no estimate that can be relied on with any degree of confidence is forthcoming, but the area under sugarcane in this district has for some years past been shown in the annual administration reports as 8,000 acres.

The subjoined synopsis of the Surma Valley experiments shows the area out and the weight of *gur* obtained: in Cachar, the

weights of the cane and of the juice have also been recorded. This meagre tale of experiments has been eked out by a those which were made in Sylhet in the cane harvest of 1

| District. | Number of experiments. | Area out. Square feet. | Gur obtained. lbs. | Gur per acre. lbs. |
|------------|------------------------|------------------------|--------------------|--------------------|
| Sylhet ... | 5 | 4,084 | 290 | 3,093 |
| " ... | 2 | 708 | 70 | 4,307 |
| " ... | 1 | 10,890 | 288 | 1,152 |
| " ... | 2 | 20,146 | 1,083 | 2,339 |
| " ... | 2 | 7,078 | 298 | 1,804 |
| Cachar ... | 1 | 2,304 | 43 | 813 |
| " ... | 1 | 1,260 | 46 | 1,590 |

The Cachar statistics of weight of cane and juice stand as follows:—

| | Area out. Sq. ft. | lbs. cane. | lbs. juice. | lbs. cane per 100 lbs. cane. | lbs. juice per 100 lbs. cane. |
|--------------------|-------------------|------------|-------------|------------------------------|-------------------------------|
| 1st experiment ... | 2,304 | 452 | 216 | 8,555 | 47.8 |
| 2nd " ... | 1,260 | 555 | 239 | 19,173 | 46.6 |

The Sylhet product is evidently *lilli gur*. To reduce it to the semi-solid *gur* common in the Assam valley, about 12 per cent of its weight should be deducted.

The statistics of import and consumption for the Surma valley may be considered apart from those of the Brahmaputra valley, because the traffic in sugar between these two parts of the province of Assam is *nil*. The returns of river-borne trade collected at Bhalrab Bazaar on the Megna show the following figures for sugar in the last three years:—

| | Imports. | | Exports. | |
|-------------|---------------------|--------------------|--------------------|------|
| | Refined sugar. mds. | Coarse sugar. mds. | Coarse sugar. mds. | Ind. |
| 1880-81 ... | 14,140 | 60,283 | nil. | |
| 1881-82 ... | 12,956 | 79,354 | 1,420 | |
| 1882-83 ... | 21,306 | 103,909 | 1,373 | |

Besides the small export towards Bengal, about 1,200 maunds of coarse sugar are yearly drawn from the Surma valley by the Khaai and Jaintia hills.

The average consumption of sugar per head of population is estimated at 4 chittacks a month in Cachar, i.e., 6lbs. a year, but this seems low. Certainly Sylhet, with its large Mahomedan population, should not consume less *gur* per head than the Assam Valley. Assuming, therefore, an average of 10lbs., and dealing with coarse sugar only, we can make the following calculation:—

| | |
|--|------------|
| Population of Sylhet and Cachar ... | 2,282,867 |
| One year's consumption of sugar ... | 22,828,670 |
| Deduct net imports of 1882-83 ... | 8,338,341 |
| Remains to be provided by the produce of (say) 9,000 acres ... | 14,490,329 |
| Thus the average produce per acre ought to be ... | 1,600 |

Whether sugarcane is really more productive in the Surma Valley than in Assam proper, we have no means of judging with certainty. There is, however, nothing improbable in the supposition, considering the density of the population in parts of Sylhet, and the known fact that an acre of land yields more rice in Sylhet or Cachar than in the Assam valley districts. The custom of borrowing money to buy manure in Sylhet, if it prevails extensively, seems also to point to a more careful style of cultivation.

The value of the sugar produced in 1882-83, as thus estimated in quantity, and taking the price at Rs. 4-8 the maund, would appear to be about eight lakhs of rupees: at the same rate, the sugarcane crop is worth 80 rupees the acre, a sufficiently probable valuation, though evolved from data extensively coloured by conjecture.

E. STACK,
Director of Agriculture.

SELECTIONS.

AGRICULTURAL EDUCATION IN CEYLON.

WE append the new scheme for Agricultural Instruction in Ceylon drawn up by Mr. Green, Director of Public Instruction. It has now been sanctioned by the Executive Council, and it is well that our readers should know exactly what is officially sanctioned. Many people already say that Part II of Mr. Green's scheme will be a failure, because though the Native Agricultural Society may agitate, yet no actual support will be given to anything practical, and no young men will come to the school of agriculture for fear of being "made coolies of." We trust this unkind way of forestalling failure may be belied, and it is well that Mr. Green has endeavoured to dispel this fear by providing for a really high English education, as well as a mere agricultural training in the school of agriculture, and if he (the Director) can further induce the Government to provide that (after a few years' warning) nobody should be made *Mudaliyar* or *Muhandram* of a Korale, unless he has some knowledge of agriculture, then we feel sure the school will soon fill. If it fills and succeeds, the Director may make it

* One series of two experiments, which gave a maximum outturn of 9,000lbs. of *gur* per acre, and an average of 4,829 lbs., has not been recorded.

part and parcel of the Royal College, though separate in buildings—like "the modern side" now so common in great schools at home. Any way, if it falls the Director has clearly done his best. And let the leaders of the Ceylonese remember that Government can then say: "You cried out for Agricultural Education—we have offered it to you. If you don't take it, why, don't complain of Government doing nothing more." We are, however, not without hope of success,—and for the following among other reasons:—We learn that the result of Mr. Green's speech at Kandy at Trinity College has been that 15 applicants have come forward for 30 ploughs, and he is getting some of the light Swedish ploughs over from Saldapet, where Dr. Robertson has after a long trial reduced them to a minimum of weight and cost.

SCHEME FOR AGRICULTURAL EDUCATION IN CEYLON.

PART I.—Preliminary Education in all Government Schools.

1. Preliminary and Theoretical Agricultural Education shall be provided in all Government Vernacular and Anglo-Vernacular Boys' Schools, by means of such text-book or text-books as shall from time to time be approved by the Department of Public Instruction.

The subject of Agriculture shall be compulsory for boys in the Standards VII, VIII, VI and V, but any boy in any other Standard may take up Agriculture if he pleases.

2. Teachers under training in the Normal School shall, from the date upon which these rules come into effect, be required to pass in the text-book or text-books mentioned in clause I; and such text-book or text-books shall form one of the subjects for the annual December examination for certificates now required for Government school-masters; and no Government teacher shall hereafter receive the certificate of the Department of Public Instruction, unless he shall have been awarded at the above-mentioned certificate examination not less than 25 per cent of marks in Agriculture.

PART II.—THE COLOMBO SCHOOL OF AGRICULTURE.

3. A special school to be called "The Colombo School of Agriculture" shall be opened in January 1884.

4. For the present, the Colombo School of Agriculture will be held at Colombo in that portion of the buildings of the Normal School heretofore assigned to Anglo-Vernacular Student Teachers.

5. The object of the Colombo School of Agriculture will be to provide a superior and suitable education for the sons of native gentlemen, and more especially land-owners. With this view the teaching will embrace (1) The higher branches of English, (2) Mathematics; (3) Agriculture; (4) Botany; (5) Chemistry.

The study of Agriculture will be divided into—

- (1) *Theoretical Agriculture*, which will be taught by means of lectures, text-books, and examination papers.
- (2) *Practical Agriculture*, which will be taught and illustrated by practical lessons and experiments on a practising farm to be connected with the School.

6. The School of Agriculture shall be under the management of the Department of Public Instruction. It will be immediately presided over by the Principal, who shall be an English gentleman duly qualified, with the assistance of under-masters, native or otherwise, as occasion may require.

7. As a general rule no boy under sixteen years of age nor over nineteen will be admitted to the School of Agriculture; but exceptional cases may be specially considered by the Director of Public Instruction. Boys will have to be tested by a preliminary examination before they are allowed to enter the School.

8. Thirty boys can be taken as boarders under the immediate care and supervision of the Principal. Out of these thirty students, fifteen may be boarded and educated at a reduced charge of Rs per mensem upon the recommendation of the Government Agent of the Province in which the student resides. For the remaining boarders a monthly fee of Rs10, which will include all charges of board and education, will be charged. A limited number of day-scholars will also be admitted to the School of Agriculture; and for these a fee of Rs2 per mensem will be charged.

9. The terms and holidays of the School of Agriculture shall be the same as those of the Royal College.

10. The course of instruction at the School of Agriculture shall extend over three years, and shall be divided into three stages.

STAGE I. (FIRST YEAR.)

English.—As in standard VIII of Government English schools.
Mathematics.—Arithmetic to the end of decimals, and Book-keeping. Algebra to the end of Simple Equations, Euclid I to III.
Theoretical Agriculture.—Text-books, lectures, &c.,
Botany.—History, Physiology, and Classification.
Chemistry.—Chemical Physics and Inorganic Chemistry.

STAGE II. (SECOND YEAR.)

English.—As for Cambridge Local (Junior).
Mathematics.—All the rules of Arithmetic, Book-keeping, Algebra, Euclid books I to VI.
Agriculture.—Text-books and lectures, and practical teaching, experiments in drainage, manures, ploughing, &c., on the practising farm.
Botany.—Agricultural and Economic.
Chemistry.—Inorganic and Organic.

STAGE III. (THIRD YEAR.)

English.—As for Cambridge Local (Senior).
Mathematics.—Algebra, Euclid, Mechanics, and Trigonometry.
Agriculture.—Practical teaching on the practising farm, cultivation of a plot of ground by each student as provided in clause II.—Lectures.

Botany.—Arboricultural and Horticultural.
Chemistry.—Organic.

11. In the third stage, a particular plot of ground on the practicing farm will be assigned to each student, the tillage, manuring, &c., of which will be conducted entirely under the students' supervision and directions. No student will be obliged to work himself, unless he wishes to do so, but he will be allowed to supervise and direct a *goyya* working under his orders. Prizes will be given to those students who best conduct the working of their plots.

12. In addition to the above prizes, there will also be awarded prizes after the examinations at the end of each term to the student who obtains the highest marks in each of the subjects taught in the school, namely:—(1) English; (2) Mathematics; (3) Agriculture; (4) Botany; (5) Chemistry.

But no prize will be given for English, Mathematics, Botany, or Chemistry, unless the student obtaining the highest marks in these subjects shall have also obtained not less than 25 per cent of marks in Agriculture.—H. W. GANN, D.P.L.—*Ceylon Observer*.

A VETERINARY COLLEGE.

A PROJECT has been set on foot in Bombay to establish a Veterinary College. The initiative is to be taken by the local Government. At a meeting of the Bombay Town Council held on the 19th ultimo, the subject came on for discussion, as the Government wished to know to what extent municipal funds would be available to forward the scheme. It was decided that if the Director of Public Instruction included in the municipal budget estimates for education a sum of money towards the cost of providing instruction in the new Veterinary College, the Town Council would be prepared to consider the propriety of recommending the Corporation to sanction a grant on that account. The Bombay Veterinary College will supply a long-felt want in the Western presidency, and probably, the scheme will be worked for the purpose of supplying the districts with trained veterinarians and the military branch of the service with qualified men for mounted corps. While the sister presidency is arranging to carry out a useful public project, very little if anything is being done in the Madras Presidency to train young men for veterinary work. About two or three months ago, we alluded to the great want felt in all large towns in the mofussil for trained veterinarians, not only to treat farm stock which are frequently subject to disease, but the better classes of inhabitants who own horses are unable to secure the services of men capable of treating diseases common to horse-flesh and farm stock. Their labors will be better appreciated than that of self-constituted veterinarians.

In the School of Agriculture, in connection with the Sydapet farm, the pupils attending the veterinary class have the benefit of the lectures delivered by Veterinary-Surgeon Mills; who is also Inspector of Cattle-Diseases in this presidency. Some time ago, the Superintendent of Government Farms announced the opening of a veterinary class at Sydapet, and it was then intended to train men for veterinary work in connection with the treatment of cattle-disease, which is prevalent in the districts at all seasons of the year and to the effects of which thousands of farm stock succumb. What has been effected in this direction we have yet to learn from official reports. It was intended to post veterinarians to the different districts after they had passed the necessary examinations at the School of Agriculture, to supply them with medicines to distribute among the owners of cattle, to impress upon them the necessity of adopting measures immediately on the appearance of disease, to segregate cattle, to avoid the rude and dangerous practice of large flocks of sheep and goats suffering from disease being allowed to stand for hours together in running streams near villages which are often the only sources of water supply of the people, and of otherwise doing away with old and effete systems for treating cattle disease. If trained veterinarians have been sent to the districts and if they have been able to achieve anything, it is time that that little was made public. There are districts in the presidency where cattle disease in some form always exists. Permanent veterinarians are required—or if it is not possible to post one qualified man to a district, there may be one for every two or three districts. The existing practice is that when cattle disease, in the form of rinderpest or foot-and-mouth disease, makes its appearance, to order the Inspector of Cattle-Diseases, or a qualified officer from the Sydapet farm to the infected locality: but by the time the veterinary officer arrives at the scene the disease spreads, or it has done its work of destruction among cattle and the labors of the inspecting officer are directed to the issuing of instructions to owners of farm stock to avoid further outbreaks. If district veterinarians have been appointed to the mofussil and are carrying out useful work, it will be of public interest to make this fact widely known.

Apart from the duties that devolve upon district veterinarians to look after farm stock, the demand for qualified men to treat horses and cattle belonging to private people is great. In all large towns the number of European residents is steadily on the increase, and with the opening of railway stations, factories, and other industries, the wants of the residents in this respect are gradually making themselves felt. Before the introduction of the Town Improvement Act in the districts, there were hardly any taxable draught cattle in large towns. With the increase in the number of horses the want of qualified veterinarians is felt, and there is no question that owners of horses have been compelled to send valuable animals to Madras for treatment. There is a promising field for well trained veterinarians in mofussil towns. "Hindu horse doctors," as they are called, are now almost

unnoticed, their occupation is going if it has not already gone. It is not an unusual circumstance for a mofussil resident to complain that he has lost a valuable horse or pony or a good specimen of draught cattle owing to the defective treatment received at the hands of itinerant veterinarians who, like village physicians and quacks, ought to be gradually improved off the face of mofussil towns. If a public association or society like the one which celebrated the fourth anniversary of its establishment the other day were to induce a few Eurasian lais to acquire a knowledge of veterinary science, some good work might be accomplished, and a new field of employment opened out to persevering and steady young men.—*Madras Standard*.

INDIA AS A WHEAT COMPETITOR.

WE have prided ourselves upon the supremacy of our agricultural interests in this country and in the conviction that Europe is dependent upon us to supply whatever deficiency she may experience in her food products, which has usually been fully equal to our surplus. But it is useless to shut our eyes to the fact that India is rapidly coming to the front as a wheat-producing country, and is already sending to the British markets a considerable amount of wheat, with every indication that in the by-nomans distant future the quantity grown and exported can be almost indefinitely increased. Hitherto the chief obstacle to wheat production and export from India has been the lack of transportation facilities from the interior to shipping ports. But this is being remedied by the building of railroad lines, opening up the interior provinces, not as in this country by private capitalists as a business enterprise, but by the Government as a necessary Government measure. The Government of Great Britain is in a measure paternal. That of India is still more so, and of necessity since the great mass of its population is always so close to the border of pauperism and starvation that the care of the Government must be constantly exercised in its favor. Hence the building of railroad lines to open up agricultural districts to the markets of the world is regarded as entirely legitimate, and within the proper province of the Government. Under this system interior provinces remote from shipping points are being opened solely with the view of furnishing an outlet for wheat which can be produced for the European markets. The first exports of Indian wheat were made only fifteen years ago. In 1875 the export only amounted to 1,500,000 bushels. In 1878 it was 4,000,000, and in 1881-82 it was 37,000,000, or nearly half the amount which Great Britain requires to supplement her own crops. The cheapness at which wheat can be produced in India, with its cheap labor, is an important element in the problem. According to the *British Trade Journal*, the cost of production does not exceed from sixteen to twenty cents per bushel, or less than half the cost of production, under the most favorable conditions, in this country. The quality of the wheat grown is also another important element. It is claimed to have a thinner bran and to make a larger per cent of flour than either the English or American wheats, some varieties giving from 77.5 to 80.5 per cent of flour, against 65.2 from English and 72.2 from American wheat. The ocean freights from Indian to Europe are greater than from our Atlantic ports, but not greater than from our Pacific ports which furnish quite a percentage of our export wheat. The staple food of the great mass of the population of India is rice, not over 10 per cent being regarded as consumers of wheat. This being the case there would, unless the habits of the people greatly change, be a much larger per cent of any given crop for export than in this country, where wheat furnishes a staple article of food for almost our entire population.

Is there anything to cause alarm to our farmers in this outlook for our surplus wheat in the future? Not as it seems to us. Our population is increasing at an unprecedented rate, requiring each year larger amounts of wheat for home consumption. Excepting as a crop on newly broken lands, we do not regard wheat-growing as by any means the best use to which the farmer can devote his lands. Constant cropping with wheat causes a rapid deterioration of the soil as has been demonstrated in every wheat-growing country. As the country grows older, wheat production instead of occupying the front rank falls to the rear, other crops, stock or dairy, taking its place to the greater profit of the farmer. In the production of meats and their products we, with our rich grazing and meadow lands and our mammoth corn fields, can compete with the world. The same is true of dairy products. Even should India with its ten-cents-a-day rice-fed labor finally capture the wheat markets of Europe, the American farmer will still find profitable use for his land in other directions. The development of sorghum-sugar production to the supply of our domestic consumption would alone save to the country as large or nearly as large an amount of money as we now receive from our exports of wheat to Europe.—*Farmers Review*.

PANDANUS; OR, SCREW-PINE BREAD.

THE *Pandanus*, or screw pines, are a most interesting group of endogenous plants, somewhat palm-like in their habit. They are either shrubs or trees, with numerous adventitious roots, which often, in local wholly support the tree after the main or true root has rotted away. They have long, imbricated, amplexicaul leaves, the margins and backs of which are usually spiny. The fruits are either fibrous drupes, collected in parcels, or berries; in the drupes the seeds are solitary, in the berries numerous.

The best known examples of this order are *Caribodorea Pandanus*, and *Nipa*; although, by some authors, *Caribodorea* and *Nipa*

are taken as typical genera of natural orders. (See Dr. Hooker's edition of Le Moout and Decaisne's Botany.)

The genus *Oarludovicæ* is confined to South America, and the so-called Panama hats are made from the leaves of the *C. palmata*.

The *Nipa fruticans* is a common object in the salt marshes of the islands and coasts in the Indian Ocean, and is a low stemless plant, palm-like in habit. The leaves are most extensively used as a roof thatch, for which, indeed, they are admirably adapted. When burnt the leaves yield salt, the spathe yields toddy, syrup, sugar, vinegar, yeast, or spirit, at the will of the operator. The seeds are edible, being somewhat like coconut in taste, the slight insipidity in taste being corrected by sugar.

The true *Pandanus* are, however, the more interesting. Of the genus *Pandanus*, there are several species, confined to the Eastern hemisphere, being very numerous in the Indian Archipelago, found principally in the vicinity of the sea, and forming one of the "aspects of vegetation." To clear one's way through these almost impenetrable masses, requires a strong arm, a good belt-axe, and, above all, a good temper. Some of the *Pandani* run from 10 to 15 feet in height. The leaves are long, narrow, tough, and leathery, with the edges and midrib armed with sharp recurved spines, which have a most provoking way of intruding in one's clothes or flesh, putting one in mind of the "wait-a-bit" thorn of African travellers. The fruit consists of a number of wedge-shaped drupes, clustered often into large coal-like heads. The aerial roots, too, with their cup-like spongioles, are very remarkable.

The leaves of the *Pandanus utilis* of Mauritius are made into sugar bags, and often are utilised in this country as fish baskets. The fruits of *P. fistidus* are extremely fetid, whilst those of *P. odoratissimus*, are, as the name would imply, the reverse. It is, however, in the Nicobar Islands where the *Pandanus* is fully appreciated, and holds a position almost equalling that of the coconut in Ceylon as a source of food.

In the Nicobars, the *Pandanus* grows to about thirty feet in height, and luxuriates on the banks of creeks and marshy ground, and almost equally as well on undulating grassy plains in the interior. The cone, or head of drupes, attains a length of fourteen to fifteen inches, and a breadth of nine to ten inches, being first of a dark green colour, changing to a dull red on ripening. The ripe fruit is gathered by the natives, the finer sorts being selected for breadmaking, the interior being given to the pigs. The drupes are then separated from each other, and placed in a large earthen vessel, which, when about two-thirds full of nuts, is set on to boil for twelve to fourteen hours, the nuts being kept covered with water during the time. After boiling, the soft dough-like substance which the drupe contains has next to be removed, and is effected in the following manner by women:—They take a shell, and drawing the fruit with some amount of pressure over the edge, force out the amylaceous matter into the shell, which, in the meantime, is held firmly between their toes. The conical-like fibrous brush left is discarded, and fresh fruits treated in the same manner, till a sufficiency of "dough" has been expressed, which is of a pale brownish colour, and largely mixed with portions of the fibrous husk of the fruit. These fibres have next to be removed. To do this, the woman, selecting a long piece of fibre, seats herself on the ground, and fastens one end of the fibre round her right toe, and the other end round one of the fingers of the left hand. Taking the ball of dough in her right hand, she passes the long fibre through it, and dexterously removes all the fragments of fibre, without wasting a particle of the dough.

This dough is either eaten in its present state with fish, or pork, or is made into rough cakes and baked on hot ashes. It forms a very nutritious food, but its peculiar sweetish taste cloy on the appetites of Europeans, though, as a substitute for bread or biscuits, or in the form of a pudding, with the addition of sugar or jam, it is by no means to be despised, and to the Nicobarees, who are not an agricultural race, the fruit of the *Pandanus* is a most valuable staple article of food.—*Journal of the Society of Arts*, September 15.

AGRICULTURAL EDUCATION FOR THE INDIAN PEOPLE.

NOT very long ago, we offered a few observations on the subject of Scientific Agriculture; and we now purpose following up those remarks with some more on what there can be no doubt is a matter of the utmost moment to the national progress and development of the Indian peoples.

As we stated in our former article, we are, and have long been, among those who hold that the country is neither socially nor pecuniarily fit for the introduction of any such of the reforms in its agricultural system as those we see Government endeavouring to introduce into the 'practising' departments of their Agricultural Schools and Colleges. Not only this, we go further and say that the way in which the powers-that-be have gone to work in the direction of teaching their native subjects to improve the husbandry of the country is hardly the best, if it is not one of the worst, method of executing a peculiarly delicate and difficult piece of business. Leaving aside the remarkably conservative tendencies of the average Hindu cultivator, and the close consequent nearness to impossibility in getting him to take to anything new (which is not on the face of it profitable), it appears to us a little too much to expect that the sending out of a mere handful of young men, with a few years' training, however excellent, among their unscientifically agricultural brethren is likely to produce any great or lasting results. On the contrary it appears to us that the effects of such a

system would be just the other way. Your first-class B. A., for instance, is hardly looked up to with any great respect outside his own clique or college; and yet look at the amount of money he costs the country; and think, too, of the high hopes which were held by the early champions of the higher education system, as to the graduates of Indian Universities creating a new era, and a glorious one in the history of this country. Well, what guarantee, we ask, have we that the expensive further out-turn of our Agricultural Colleges will be a bit better, so far, we mean, as regards any influence for good on the masses of their fellow-countrymen? We are particularly anxious that we should not be misunderstood. We are by no means of Professor Mount Williams' way of thinking that the average 'educated native' is more or less of an "incarnate curse." On the contrary we are distinctly of opinion that the educated classes of the native community form by far the most hopeful, important, and interesting section of the entire Native Indian Commonwealth. All that we do say, and none could wish more earnestly than we do that we were mistaken, is that the 'educated native' class has not, as yet, been productive of any palpable influence for good on the great bulk of his unenlightened compatriots. Holding, as we have been forced, by experience and observation, to hold, this painful belief, we are most anxious to do what little may lie in our power to prevent the occurrence of similar mistakes, and the foolish, if not positively useless, outlay of money on (so-called) educational schemes.

To hasten on, however, to our subject itself, we may state that we fully admit the correctness of the principle that the agricultural condition, interests, and prospects of so almost entirely an agricultural country as this should occupy no small share of the most careful attention of the authorities; but, knowing that the country is in a greatly impoverished condition, it becomes necessary to consider in what direction steps should be taken with the least possible expense, as well as with the greatest possible benefit to the agriculturalist population.

In the first place, it seems to us above all things necessary that any movement in the direction of agricultural reform in this country should take a thoroughly practical direction. Instead of putting the country to the cost of maintaining expensive Schools and Colleges for agricultural Education—which is not yet a *felt* national want—we certainly think the revenue authorities might, in the course of the constant contact into which they are coming with the agricultural classes, very properly and profitably undertake the introduction of new and improved seed grains, implements, and even cattle. Something of this kind was tried—with success, if we remember aright—during the famine of 1876-77; and we only wonder why the experiment has not been made more largely and more generally.

We should also like to see some of our veteran Anglo-Indians settling down to a farmer's life in such places as Bangalore or Coimbatore, where the climate is not so trying to the European, and show their able neighbours how to do farm-work in a better fashion than that now in vogue. We are sure the example will produce substantially beneficial results. Practice, all the world over, is a far more impressive teacher than precept, as is abundantly proved by the many good (and many bad) things our native fellow-subjects have learned or copied from us.

Such are some of the ways in which, we venture to think, the Government could, more easily and economically, as well as more effectively, do something worth doing for the improvement of Native Indian Agriculture; and we trust they may commend themselves to those who have it in their power to adopt the same in practice, as well as to all those interested, like ourselves, in the discussion of a subject most intimately connected with the progress and prosperity of this greatest dependency of the British Crown.—*Mudras Athenæum*.

SHEEP HUSBANDRY.

PRESIDENT GIBSON, of the Montana Wool Growers' Association, delivered an excellent address at the late annual meeting of that organisation. What he said pertaining to the rapid development of the wool industry in the United States and the difference in price between Australian fine wools and those of the great wool growing regions west of the Mississippi river may be read with profit by wool-growers generally. It is as follows:

"The rapid development of the wool-growing industry of the United States and its territories must satisfy any thoughtful grower that soon more wool will be produced than can be used in the woollen mills of the country. Next to Australia, we are now producing more clothing wool than any other country on the face of the earth. In 1878 our wool product was 115,000,000 pounds, while the present year it will not be far from 350,000,000 pounds. Should this ratio of increase be maintained, you will perceive that the clip of the country will soon reach the enormous quantity of 500,000,000 pounds, nearly all of which is clothing. When we produce more wool than is required to supply our looms, we must export our surplus, and prices will then be fixed by the great market of London, as well as that of Boston. This may not be pleasant to contemplate, but we must be ready for this juncture of affairs, for it will surely come soon. We are now importing, I believe, scarcely 50,000,000 pounds of clothing wool per annum. How can we best prepare for the new conditions of things? Plainly by a more thorough knowledge of our business. We must, if possible, grow our wools at less cost. The all-important point to be gained, however, is the production of wool here in Montana that shall, from its superior condition, take the lead in the American market. Our wool is to-day worth 20 to 28 cents in Boston, while Australian and New Zealand wools are worth 40 to 45 cents. Australia may be a more favored spot for growing wool than Montana, but I doubt it. I find here these subtle influences—whether they spring from the soil, the water or the atmosphere—

that produce the softest and most brilliant clothing wools. I know, from the fact that our wools lead all other territorial wools in the market, although this was the last of the territories to commence wool growing, that nature has kindly given us advantages that she has withheld from other sections of this continent.

Whence, then, arise the wide difference between the English colonial wool referred to and the wool of Montana? Clearly from the difference in breeding and in the manner of preparing the wool for the market. In buying sheep, we are too apt to put them all in the same scale of prices—coarse, medium, and fine. With too many of us it is a question of number, instead of quality. We recognize but little difference between mongrels and the pure descendants of the importations of Humphreys and Jarvis. We commence breeding up and then breed back to where we started from, each grower breeding "on his own hook," regardless of what his neighbours are doing. The result is that in the same district you will hardly find two clips of wool at all alike, and in the same flocks are all grades, from the soft, beautiful XXX wool, down to a coarse, frowy fleece, fit only for low carpet filling. The average Australian wool grower is constantly improving his hands by the most careful selection. The whole world is ransacked for the choicest and hardest strains of Merino blood. Vermont annually furnishes a large number of the very best stock rams for English wool breeders, whose stock ranches are ten thousand miles distant. They have thoroughly tested the different types of Merino sheep, and they obtain the best, regardless of cost. Can we wonder, then, that the English colonial wool growers have built up during the present century such a magnificent wool industry in Australia? If we would bring Montana wool to the very front rank at the eastern seaboard and create a brisk demand at paying prices in the face of competition of the best wool growers of foreign countries, we must improve its quality by adopting rules of breeding and of flock management heretofore unknown among us. We must weed out our inferior sheep as fast as we can, and send them to the shambles. The best we have must improve by introducing the choicest blood. Fortunately, we in our own country, in the Eastern States, a type of Merino sheep that stands second to none in the world, from which we can obtain, at reasonable prices, stock suitable for the highest improvement of our flocks. At the London wool sale the shrinkage of every lot offered is accurately given and guaranteed, and this method must soon be adopted in our own country. Manufacturers are naturally prejudiced against heavy wools, and consequently they are the last to be sold. Light shrinking wools are always attractive, are sold quickly at full market values. While I am opposed to the introduction of greasy, wrinkly Merinos, I would not be understood as favoring the Saxony or Silesian type of Merinos for Montana. I would recommend a class of Merinos occupying a place between the two extremes. For some of the pure bred flocks of Vermont, Ohio, or Wisconsin you can always select strong, vigorous rams, carrying no wrinkles or folds except upon the neck, and whose wool bears no excess of oil. "When the time comes that the United States produces more wool than our manufacturers require, it will then become among our wool growers a question of the "survival of the fittest." Wool growing, in my opinion, will increase and continue to be a remunerative business in the great pastoral district adjacent to the Rocky Mountains, from Mexico to the British dominions, while the Merino sheep industry at the East will give place to more profitable pursuits or be supplemented by the mutton races, such as the Southdowns and other Downs. The latter theory would seem to be correct when we consider the wonderful growth of the cities from the Atlantic to the Missouri river, and the rapidly increasing demand for choice mutton.—*Breeder and Sportsman.*

THE HIGHLAND SOCIETY'S EXPERIMENTAL FARM.

SEVERAL members of the Highland and Agricultural Society lately visited the experimental station of the society at Pumpherton. The weather was favourable for the excursion. Among those present were Sir James Gibson Craig, Bart.; Mr. Colin Mackenzie, of Portmore; Dr. Aitken, Edinburgh; Mr. Scott Dudgeon, Longueuxton; Mr. Wm. Dingwall, Ramornie; Mr. H. Lindsay, Meadow Flat, and Mr. Todd, the manager of the station. Dr. Aitken, the consulting chemist of the society, conducted the party over the station, explained the nature of the experiments, and pointed out the more noteworthy results. The field in question, which has been under experimental tillage during the past six years, is, like the other stations similarly dealt with, 10 acres in extent, and is divided into 40 plots of 1 rood each. The cropping is a rotation of turnips, barley, grass, and oats, and the chief object of the experiments is to determine the crop producing value of various forms of the most important manures. The manures on each plot contain 40 lbs. phosphoric acid, 30 lbs. potash, and 10 lbs. nitrogen. It is in the form in which these have been put on that the difference lies. For the present crop of barley the ground, which is a thin, cold clay, was ploughed on the 15th January and 17th and 19th February, and the barley sown on the 23rd April. The manure was sown on the 28th April, and the first braised was seen on the 12th May, and nitrate dressing on a portion of the area being applied on the 10th June. From the date of sowing to the present time the rainfall has been 13.15 inches, there having fallen from 23rd April to the end of the month, 1.07 inches; during May, 1.65 inches; June, 2.44 inches; July, 4.98 inches and during August 3.11 inches. The mean temperature of May was 57 degrees, of June 59 degrees, of July 67 degrees, and of August 63 degrees. Twelve of the plots had been treated with phosphatic manures, six with nitrogenous manures, four with potash manures, four with guano, and three with superphosphates, while the remaining plots had been treated with these and other

manures in various quantities. The results, in many instances, were very marked, particularly in the difference between the dissolved manures. Dr. Aitken pointed out that the dissolved phosphates showed an advantage over undissolved phosphates in two directions—namely, that they produced a larger and an earlier crop than the undissolved. In regard to the potash experiments, it was found that the application of the sulphate and of the muriate produced very equal results. As regards the nitrogenous manures, nitrate of soda (with bone ash and sulphate of potash and sulphate of ammonia) were also found to produce very equal results, and the crops treated with them were very good. In the plot in which 'shoddy' had been applied, the crop had evidently not yet felt the benefit of the manure. In an adjoining lot it was found that dried blood had produced a very excellent crop, and it seemed evident that if it had been put on a little earlier, the crop would have been one of the very best in the station. There seemed to be little difference in the results obtained from fish and Peruvian guano, which produced good crops; but the Iobasco guano had not quite come up to the mark of the other two. Where no nitrogen had been applied there was found a ripper crop than where nitrogen had been applied alone. Where nitrogen had been applied, Dr. Aitken remarked, in the form of nitrate of soda, the crop was the latest and greenest in the station, and, although not the thinnest, would never come to anything like a crop. In some of the plots one or two constituents had been withheld, and it was found that where no phosphates had been used the crop was much later, thinner, and poorer in every way. Where phosphates alone had been used, the crop was earlier, but thin. Where there had been no potash used, the crop suffered at an early period of the season, and had a 'sagged' or tulip-root appearance, and was late in shooting. Where potash alone had been applied, the crop was not so deficient as it has been in former years, but still it was very green and very late, and would never come to much. As regarded superphosphates, Dr. Aitken explained that these were applied in three different states of solubility, and although all produced heavy crops, that which was mediumly dissolved had produced the best of the three. Attention was directed to another important feature of the experiments. A large majority of the plots had their nitrogen applied at two different times. One-half of each plot had half of its nitrate of soda put on at the time of sowing, and the other half six weeks later. It was found that the half which had all the nitrate applied at the time of sowing had a much ripper and straighter crop than the other. The half which was manured with nitrate six weeks after sowing (the 16th June) had a very bulky crop—too bulky, in fact, for the land. A considerable part of it was much laid, and was later than the other. It would have been better, it was considered, if the second application had not been so late in being made. In view of the questions raised by the Agricultural Holdings Act, considerable interest was taken in two plots in which the effects of previous years' manuring, were still very visible. Dr. Aitken, while conducting the party over the field, read a letter which he had received from Mr. P. M'Laggan, M.P., who was prevented by another engagement from being present. Mr. M'Laggan wrote:—"I have been examining the experiments, and I have learnt something from them, and I have had my opinions confirmed on certain points. I observe that where nitrate of soda is applied by itself the crop is later. This I have always found to be the case. I observe that this year the crop is better where there is the largest quantity of soluble phosphates; and it is earlier where the phosphates are dissolved. I have no doubt you will be able to point out more results worth noting, and I can only regret that I shall not be present to hear them." The plot which was considered to have the best crop was one which had been treated with dissolved bone dust with muriate of potash and nitrate of soda, the crop being reckoned at 40 bushels per acre. Decorticated cotton cake had produced a very good crop, which had ripened quickly, and was regarded as much superior to the produce of rape seed dust with which another portion of the same plot had been treated.

VEGETABLE EXTRACTS.

WHILST it is admitted on all hands that the cultivation of economic plants, yielding sugar, fibres, and drugs, and their by-products of all kinds, according to the climates and soils suitable to their cultivation, might be profitable, the obstacle that the grower and the capitalist alike have had to face, has been the almost insuperable difficulty of extracting the several products at a cost of production that will leave a profit at all commensurate with the risk incurred. When we take into account the amount of unprofitable vegetable matter associated with the more valuable part of the plant to be dealt with, the cost of labour and cartage of the crude material to the nearest mill and the comparatively poor results, the costly and by no means perfect machines return upon the outlay, we are the less surprised to find how quickly the enthusiasm of the most hopeful is cooled after the first or second essay in any of these directions.

The efforts made by the Government of India to improve the condition of the fibre producers, who had expended large sums in cultivating 'china grass,' affords us a capital illustration. Their evident desire to promote on a larger scale the cultivation of plants which from time immemorial had produced valuable fibres for native textile fabrics, led the Indian Government to offer a prize of some five thousand pounds sterling for the production of a suitable machine to remove the fibre from the woody matter associated with it, in the *Bumelia* plant particularly. It was in the year 1870 the offer was made. The machine was to be of such a character that it could be used in the rainy season, when the plant was still green, at a time when the

difficulties of heating the plants are insuperable except by artificial means. The first trial was made at Saharunpore in 1872. The results obtained were considered unsatisfactory; but Messrs. D. and J. Greig received a prize of £1,500 for a crushing machine then shown. The trials were postponed for some years, and at the second contest, in 1880, no less than twenty-three competitors presented themselves. The ruling idea was a crushing machine. Exhibits from England, America, France, Denmark, Hungary, Java, New Zealand, and India were represented, but in no case could a machine be found that would "extract the fibre from the brown exterior pellicle and from the excess of agglutinative gummy matter which holds them together in such a manner as to produce an article whose value in London shall not be less than £45, and of which the cost of production shall not exceed £15 per ton of fibre obtained." Crushed stems, in fact, no matter how deftly treated by mechanical means, refuse to surrender their more delicate filaments (and these are the most prized), and only give up their coarser constituents, in a more or less mangled form, when subjected to the clumsy ordeal they have undergone. All at once, and that not so very long ago, the chemists who had been investigating the progressive action of fermentation in plants in cold and warm water, obtained a clue to the laws which seem to regulate the process of vegetable decomposition, and did not fail to observe that as the temperature was raised the adherence of the internal ligneous part and the cortical envelope is destroyed, and the separation of each of the different concentric layers which form the wrapper is effected. The fibre-bearing plant is provided with three zones in the bark, consisting of the epidermis and a thick layer of parenchyma, which contains the chlorophyllum of the plant, then a larger layer of cortical fibres, generally isolated and independent of each other; the last zone is contiguous to the cambium in which are the finer fibres, and associated with these there is an abundance of small crystals of carbonate of lime; it was found, that if the stems were subjected to superheated steam or some such calorific agent, the moisture could be drawn off effectually in a few minutes by the addition of some chemical re-agent and the fibres extracted free from any kind of adhesive particles that would render it unsaleable, there was an end to all obnoxious or tedious "retting" or "stripping" processes, and the object of their search was attained. During the last four years steady progress has been made in rendering the operation perfect and profitable, and at a cost which will be hardly felt when the value of the fibre comes to be submitted to the manufacturer; similar experiments have been made in England, France, and America. The work commenced in France by the well-known M. A. Favier has been improved upon by the distinguished chemist M. Fremy. In England much attention has been bestowed upon the subject, whilst American chemists have contributed their share. Side by side with these discoveries of such incalculable value to the commerce of the future, chemists in the north of Europe, in America, France, and England, were making equally rapid progress in perfecting new methods of extracting saccharine matter from sugar cane, sorghum and maize plants. The old and cumbrous process of extracting sugar from cane by elaborate and costly machinery, always most profitable to the manufacturer, but which after all gave only a poor return to the grower, had this effect amongst others, of forcing the production of beet root and other kindred saccharine plants upon the market in competition with our colonial trade, was admitted on all hands to be defective and unprofitable. Other means have now been found by which pure sugar and syrup can be drawn direct from the sugar-producing plants we have indicated. By this new departure costly machinery is dispensed with, and the land in some instances, without overtaxing its power of production, can be made to give a continuous yield of sugar-producing plants. Crushed cane with its poor return in sugar, molasses and trouble will become things of the past. The American Department of Agriculture, ably supported by chemists of known experience have superintended for the last four years the new method of extracting sugar by a simple chemical operation, and at a cost which, including the cultivation of the plants, at first sight may seem simply incredible, until the tables of expenditure and profits are consulted, when all doubts are dispelled by the evidence they contribute. It appears by the published report of the United States Department of Agriculture at Washington that—"Eighty batches of syrup taken by the manager from the crusher in the consecutive order of production made from cane and stems of all conditions, good, bad, and indifferent, show an average of 66 per cent of crystallized sugar. Several of the best show as high as 80 per cent. All would have shown this high average if all the cane had been good." In England like results have been arrived at, as we have already shown in the pages of this journal, and it is possible when the researches now under observation and exhaustive trial have been perfected, as they assuredly will be before long, that a perfect revolution in sugar production will be effected. Nor has the investigation of methods for extracting these products by chemical means limited the field of operation; these same chemical studies have led to others of equally high commercial importance. The same or equally simple methods will be applied to the extraction of dye stuffs and other alkaloids with apparatus, which, we gather, is of the simplest and most inexpensive character.

It is not possible to estimate the enormous value of these discoveries. Their future effects upon planters' prospects is evident. A new impetus will be given to tropical and even European agriculture. The cultivation on a large scale of fibre and sugar-bearing plants, which languished of late for want of some ready means for their ultimate utilization, is obvious. Capital which hitherto has been only too grudgingly invested in such enterprises will flow into channels which undoubtedly will yield large returns. Lands which have proved capable

of producing such forms of vegetation without stint, and have relapsed into their former state of sterility, will again be taken up, and employment will be found for many who are at present eagerly looking forward to participate in the fruition of such remunerative enterprises as these, both at home and abroad.—*Planters' Gazette*, September 15.

CINCHONA.

THE GOVERNMENT CINCHONA PLANTATION IN BENGAL.

THE following is the Resolution of the Government of India, on the Annual Report of the Government Cinchona Plantation in Bengal for the year 1882-83, and the Annual Report of the Quinologist for the same years. The result of the planting operations of the year shows a decrease of about 50,000 cinchona trees on the returns of 1881-82. This is due to the uprooting of a large number of the *Oalisaya* and hybrid varieties which were found to possess bark of poor quality. Some 160,000 red-bark trees were also uprooted in the ordinary rotation, and were replaced by the yellow bark and hybrid varieties. Nearly all the land within the existing cinchona reserve [suitable for cultivation has now been planted out, and the Superintendent accordingly applied, in October last, for permission to plant out with *Ledgeriana* and the hybrid variety a tract of land in the trans-Teesta portion of Darjeeling which had been reserved for Government cinchona cultivation. Both these species have been proved by repeated analyses to be very rich in quinine, while most of the yellow bark or quinine-yielding trees on the existing plantations at Mungpoo are quite young, and the whole stock is not sufficient to furnish, even when mature, enough bark to employ the factory profitably for more than a few weeks in the year. There is, in fact, no plantations of these trees actually in existence, while the nurseries have a magnificent stock of nearly half-a-million plants of the best sorts of yellow-bark trees which would be lost unless the seedlings were speedily planted out. The proposal for forming the new plantation was readily approved by Government, and measures have since been taken for planting out the reserve with a number of the best kinds of *Ledgeriana* and hybrid cinchonas.

In the Resolution recorded upon the proceedings of last year, it was remarked that there were several distinct forms of the hybrid variety, and analyses were given of the samples of bark of four of these forms. During the year under review the Superintendent had analyses made of four more of these forms, and the results obtained from all the eight hybrids are compared in the following table:—

| | No. 1. | No. 2. | No. 3. | No. 4. |
|--|---------|---------|---------|---------|
| Crystallised sulphate of quinine | 2.87 | 1.48 | 1.88 | 0.97 |
| Crystallised sulphate of cinchonidine | 2.94 | 2.83 | 2.93 | 1.94 |
| Crystallised sulphate of quinidine | Traces. | Traces. | Traces. | Traces. |
| Cinchonine (alkaloid) | 0.72 | 0.67 | 0.52 | 0.80 |

| | No. 5. | No. 6. | No. 7. | No. 8. |
|--|---------|---------|---------|---------|
| Crystallised sulphate of quinine | 2.12 | 2.04 | 6.12 | 3.99 |
| Crystallised sulphate of cinchonidine | 2.84 | 2.26 | 2.46 | 3.33 |
| Crystallised sulphate of quinidine | Traces. | Traces. | Traces. | Traces. |
| Cinchonine (alkaloid) | 0.33 | 0.68 | 0.55 | 0.57 |

Dr. King points out that hybrid No. 4 is very poor quinine, and it was the trees of this sort that were uprooted during the year. No. 7 appears to be exceptionally rich in quinine, and the plantations of this variety might with advantage be extended.

The total number of cinchona trees of all sorts at the close of the year was 4,711,168, namely, red (*Cinchona Sucoirubra*) 3,713,200, yellow (*Oalisaya Ledgeriana*) 662,926, hybrid unnamed variety 304,378, and other kinds 30,592.

It is satisfactory to observe that the crop of the year is the largest that has yet been harvested on the plantations. It

amounted to 396,980 pounds of dry bark, of which 372,610 pounds were of *Succirubra*, 23,120 pounds of *Calisaya* and *Ledgeriana*, and 2,250 pounds of hybrid bark. By far the largest portion of the produce was made over to the factory for conversion into cinchona febrifuge, while about 41,8000 pounds of yellow and red barks were sent, at the request of the Secretary of State, to London to be there converted into various forms of febrifuge, and returned to this country for trial by the Medical Department.

The expenditure on the plantations amounted to Rs. 80,739-8-2, against the budget allotment of Rs. 82,225. Of this expenditure Rs. 17,548-3-9 was incurred on the newly-opened trans-Taseta plantation, and on the young plantation at Sittong. This sum is chargeable to capital account. The balance, amounting to Rs. 63,191-2-5, which was spent on the old plantation, and includes charges on account of packing and carriage of bark sent to England, is chargeable as working expenses.

It is disappointing to notice the continued failure of *Carthagena* bark, notwithstanding that the utmost care has been taken of the plants and every endeavour made to grow them at various elevations and with various exposures. Only three plants were alive at the close of the year. An attempt has been made by the Superintendent to introduce the *Remija* plant, which is a genus botanically allied to cinchona. It is said to be less particular than cinchona as to soil and climate, and produces a quinine-yielding bark under the name of *Ouprea*. This bark forms a very large proportion of the quantity of quinine bark imported into Europe. Although the first attempt to grow the plant in the Mungpoo plantations has not been quite successful, Dr. King entertains hopes of successfully acclimatizing it, when he is able to procure a more adequate supply of seed. The Lieutenant-Governor will await the result of the experiment with much interest. The surplus seed of the *Calisaya Ledgeriana* was, as usual, distributed during the year gratuitously amongst applicants.

Dr. King has eventually succeeded in obtaining an analysis of the bark renewed on *Succirubra* trees that had their original bark removed by the shaving process introduced by Mr. Moens, the distinguished Director of Cinchona Cultivation to the Dutch Government. It appears that this process consists in shaving off the greater part of the bark of a living tree to the height of from 8 to 10 feet from the ground, care being taken to leave everywhere a sufficiently thick layer of bark to cover the wood. This method has had a fair trial on the Sikkim plantations, and the result has, beyond doubt, been favorable as the bark renews perfectly. What, however, remained to be seen, was whether the renewed bark was as rich in medicinal alkaloids as the original. It was with this object of determining this question that the analysis above referred to was undertaken during the year. The results are thus described by Dr. King: "The bark renewed rather slowly, but the analysis shows that it is very rich both in quinine and cinchonidine; and there can be no doubt that in countries where red-bark trees are perfectly at home, and where their continuance in good health and vigour for a long series of years can be absolutely counted on, this shaving process must be a very excellent one."

An interesting feature in the operations of the year is the low cost at which the febrifuge was turned out. The price of the febrifuge necessarily fluctuates from year to year, but in no former year has it been so low as Rs. 8-8-0 a pound. This satisfactory result is attributed chiefly to the larger percentage of the alkaloids (2-73) extracted from the bark used in manufacture. The issues, however, fell below those of 1881-82, though they were a little in advance of those for 1880-81. The following table compares the distribution in the past three years:—

| | 1880-81. | 1881-82. | 1882-83. |
|--|----------|----------|----------|
| | lb. oz. | lb. oz. | lb. oz. |
| To Medical Depot, Calcutta | 3,000 0 | 3,386 0 | 2,000 0 |
| Do. do. Bombay | 2,000 0 | 1,000 0 | 1,000 0 |
| Do. do. Madras | 500 0 | 800 0 | 350 0 |
| To Colonial Government, Mauritius | ... | ... | 150 0 |
| To Surgeon-General for District Medical Officers of Bengal | ... | 995 4 | 803 12 |
| To Inspector-General of Jails for Jails and Look-ups, Bengal | ... | 14 12 | 26 12 |
| Sold to the public | 3,150 11 | 4,680 0 | 4,560 12 |
| Given as samples | 3 2 | 2 9 | 10 0 |
| Total | 8,653 13 | 10,878 9 | 8,901 4 |

The issues to the public were 120 pounds below those of 1881-82, and not in excess of that year, as stated in the Superintendent's

report. The stock of febrifuge in hand on 31st March 1883 amounted to 2,062½ pounds, which, though greater than that with which the year opened, is by no means too large a reserve to meet emergencies.

The revenue derived from the sale of the febrifuge, seed, plants, and bark amounted to Rs. 1,52,807-1-0—

| | Rs. | A. | P. |
|--|----------|----|----|
| By sale of febrifuge, seed, plants, and bark to the public | 80,577 | 9 | 0 |
| By credits from the Medical Depot of Calcutta | 33,766 | 0 | 0 |
| Do. do. do. of Bombay | 16,500 | 0 | 0 |
| Do. do. do. of Madras | 5,775 | 0 | 0 |
| Do. from Colonial Government of Mauritius | 2,475 | 0 | 0 |
| Do. from the Surgeon-General Bengal | 13,271 | 8 | 0 |
| Do. from the Inspector-General, Jails | 442 | 0 | 0 |
| Total | 1,52,807 | 1 | 0 |

The operations of the year resulted in a profit of Rs. 66,284-9-5, which is equal to a dividend of 6½ per cent on the capital outlay. This is exclusive of the cost of a considerable quantity of the bark sent to the Secretary of State which has not been taken into account. It must, moreover, be borne in mind that these profits do not represent the whole of the gain of the year. The cost of an equal quantity of quinine at Rs. 86 per pound would have been Rs. 4,01,328. The cost of the febrifuge used was Rs. 68,988-8-0. There was thus a saving of Rs. 3,32,340. The total saving effected since the opening of the factory by the substitution of the febrifuge for sulphate of quinine amount to Rs. 23½ lakhs, which is more than twice the amount of the cost of the plantations.

Considerable attention was given during the year to the improvement of the process of manufacture. The present system is admittedly wasteful, in that it fails to convert into febrifuge the whole of the alkaloids which the bark contains, while there is no doubt that by the adoption of a different and more costly process of manufacture a still larger percentage of the medicinal alkaloids could be extracted. It is not, however, equally certain whether the febrifuge so obtained could be turned out at a less cost per pound. The whole subject of the course to be adopted in the disposal of the raw produce of the plantations is still under the consideration of Government.

THE SIKHIM CINCHONA PLANTATIONS.

TO any one visiting the Darjeeling district, an expedition to the Government Cinchona Plantations is most interesting. Mungpoo, where Mr. Gammie lives, is about 17 miles from Kurseong. The road runs a long the top of a ridge of the mountains for a considerable distance and is a beautiful ride. It is mostly through forest, abounding in ferns and orchids of infinite variety, and of difficult forms to those commonly found in Ceylon. The Government cinchona plantations occupy a vast stretch of country, and are under the charge of several Europeans. The soil is in most places very rich and remarkable free and porous, whilst the general features of the country are steep and bold to a degree. The most noticeable plantation is one of hybrids near the superintendent's bungalow. These trees are about four years old, and are raised from seed of the original hybrid or "Ignota" trees which appeared in the parcel of seed formerly sent from Hakgala to Darjeeling. Eight forms are recognized amongst these trees as being distinct and characteristic, and representations of each have been analyzed with the result of figures ranging from .97 to 6.12 crystallised quinine sulphate. The worst of these forms, known as No. 4, has been entirely eliminated from the plantation, so that its flowers shall not contaminate those of the more valuable kinds. It is characterized by large light green leaves, and is the form which most nearly resembles *succirubra* in appearance. The richest form, No. 7, giving 6.12 crystallised quinine sulphate, is a small broad-leaved free-growing tree, with some officinal characteristics. At a considerably lower elevation than this is situated the famous *Ledgeriana* plantation. These trees are not as large as one would expect from their age, they having been raised from cuttings of the original trees from Ledger's seed. Their most remarkable characteristic is the great girth of the stem and the extreme thickness and weight of the bark, which can be taken off literally in slabs. These trees were all covered with blossom when I saw them, and promise a very abundant crop of seed shortly.

In another portion of the plantation is a *Ledgeriana* clearing, the plants in which were raised from seed. A strange feature in this planting is the large number of *Calisaya javanica* amongst the

ruo *Ledgerianae*. They are, although only about three years old, blossoming profusely, and are easily recognizable by their large flowers and flower branches. The general appearance of the cinchonas is rather disappointing, the growth not being equal to what we are accustomed to in Ceylon, but the wholesale dying out to which we are so liable appears to be little known. I hear canker is very common, but it is purely local in its effect and does not necessarily kill the tree, or materially affect its growth. Mr. Gammie has found a marked falling-off in the growth and general health of the cinchonas, the original trees being superior in every way to those raised from them, and the successive planting being each inferior to its predecessor. This appears to be a very general impression in Ceylon, and it is interesting to note that, in spite of the extreme care and liberal expenditure bestowed in the Government cinchona gardens, this experience in regard to them has been the same as in our case. As with us too, the hybrid cinchonas are markedly superior in growth and general health to the *succirubras* alongside them, and in consequence, their more valuable forms are alone being propagated in addition to the *Ledgerianae* which occupy the first place. The system of cultivation pursued is what has been described before except that hoeing is dispensed with. The jungle is allowed to grow freely under the trees and is kept within bounds by periodical "cuttings." Terracing has been tried, but was not found a success, and the terraces are now being levelled in consequence. All the plantations hitherto are on what we should call "chena" land, but the soil is so rich that the trees do not appear to suffer in any way from exhaustion of soil. The cold tweather of last winter, which damaged the branches of the forest trees near the Darjeeling station to such a great extent by the weight of snow on them, appears to have killed back many of the *succirubra* primaries, which have a strange appearance in consequence. It is striking that in spite of the wonderful financial success of this undertaking, and of the Darjeeling Cinchona Company, which exactly faces Rangbée and Mungpoo across a wide and deep valley, none of the Darjeeling Companies have embarked in cinchona cultivation to any great extent. A few young trees are to be seen along road sides in some places, but anything resembling what we should call a clearing is unseen. It is no doubt fortunate for us in Ceylon that this cultivation has not been largely extended by private individuals in the Darjeeling district, for with the large amount of suitable land which could no doubt be found, and with the comparative immunity they enjoy from premature dying out, we should be faced with a formidable rival to what is now a struggling enterprise owing to low prices. Another point in which Darjeeling experience coincides with ours is regarding the utilisation of land for a second crop of cinchona. This appears to have been a failure when tried, and, in consequence, all such land is, in the Government territory, planted up with timber trees, and, when private land, with tea. I was told that tea planted in old cinchona land did not flush as freely as that in the original chena, but probably a more extended experience will show that when the tea roots penetrate deep into the subsoil this inferiority will disappear.

There are some very fine *Ledgerianae* plants in the various nurseries, said to be nearly half-a-million in number, and in order to dispose of these, a new plantation, at a distance of 10 or 50 miles across the Teesta river, has been formed for their reception. I was shown some plants raised from so-called "calisaya" seed sent from Jamaica by Mr. Morris, and which it now appears are ordinary officialis. It seems strange that such a mistake should have occurred, but, apparently, the Jamaica "calisaya" trees which we have heard about must be what we know as "officialis."

Carthagena bark plants have been tried at various elevations and in various localities, but without success. There was one specimen left near the bungalow which did not look healthy, and which it is to be feared will soon succumb.—*Ceylon Observer*.

THE CINCHONA INDUSTRY IN BENGAL.

WE have before us the Annual Report on the Government Cinchona Plantations in Bengal for the year 1882-83. From this we gather that the Government possess four millions, seven hundred and eleven thousand one hundred and sixty-eight cinchona trees of sorts in the sister proidency, and that these are doing as well as can be expected, considering the comparatively embryonic stage in which the cultivation of the quinine bark tree is at present in this country. The above total is exclusive of sixty-three thousand six hundred and ninety-seven trees which were uprooted during the year under review, as the analysis showed that the bark was of poor quality. Of these discarded trees twenty thousand were *hybride* and forty-three thousand six hundred and ninety-seven *calisayae*. The removal of these inferior trees

is in conformity with the policy which has been followed for some years of raising the standard of the produce of these estates by cultivating only the finest kinds of quinine-yielders. In conformity with the same policy, one hundred and sixty thousand and eight-five red bark trees, which had to be uprooted in the execution of the above system, were replaced, not by red barks, but by yellow barks and *hybride*.

The crop for the year is the largest that has yet been harvested on plantations in question. It amounts to three hundred and ninety-six thousand nine hundred and eighty pounds of dry bark, of which thirty-eight thousand eight hundred and eighty pounds were from comparatively young plants, and the rest from matured trees. Of the total crop, three hundred and seventy-two thousand six hundred and ten pounds were *Succirubra*, twenty-two thousand one hundred and twenty pounds were *Calisaya* and *Ledgeriana*, and two thousand two hundred and fifty pounds were *hybrid* bark. The crop was harvested by two methods, one hundred and eighty-two thousand seven hundred and twenty pounds having been procured by uprooting trees that had begun to mature, while the remaining two hundred and fourteen thousand two hundred and sixty pounds were got by thinning the plantations at spots where the trees had begun to crowd each other. The bulk of the crop was made over to the factory for conversion into cinchona febrifuge, but twenty-seven thousand eight hundred pounds of yellow bark and fourteen thousand pounds of red bark were sent home to the Secretary of State, by whom the consignment has not yet been accounted for. It is, we believe, intended that these forty-one thousand eight hundred pounds of bark should be converted in London into various forms of cinchona febrifuge, and that these shall be sent to this country for trial by the Medical Department. The results of this experiment should prove a great success both financially and otherwise. Including the crop of last year, the total outturn from these plantations since their formation, are, we are informed, considerably over two and-a-half millions of pounds of dry bark. The Government may therefore be congratulated on possessing a very valuable property indeed in the Cinchona Plantations of Bengal. The budget allotment for the year was eighty-two thousand two hundred and twenty-five rupees, of which only eighty thousand seven hundred and thirty-nine rupees were spent, thus leaving a balance of one thousand four hundred and eighty-five rupees on hand of the allotment. In return for this outlay, three hundred and ninety-six thousand, nine hundred and eighty pounds of bark were harvested, and delivered over to the factory at cost price. The cost price is calculated at two annas and nine pies per pound of bark. The cultivation of the *Carthagena* bark appears to have been a decided failure, as only three plants remained alive out of a large number at the end of the year. Nothing could well have been more disappointing than has been the attempt to introduce this bark. The plants when received from Kew appeared to be in fine condition, and grew at first vigorously, so much so as to lead to the belief that the species would be easy of cultivation, gradually, however, all the plants, with the exception of three, sickened and died. Every care was taken of them. Individual plants were tried at various elevations and with various exposures, but the results have been uniformly disappointing. *Cuprea*, a quinine-yielding bark, imported into the London market from South America did not give more encouraging results to the effort to domesticate it in Bengal. Out of a single packet of seeds which was all the Superintendent could obtain, only one solitary seedling was raised. We are assured, however, that this cultivation will be persisted in until the plant is acclimatised. The supplies of *Cuprea* bark to the home market have so steadily increased, that now this description of bark constitutes by far the largest proportion of the total quantity of quinine bark imported into Europe. For a long time the botanical origin of *Cuprea* was unknown, but it is now ascertained to be the produce of a species of *Remija*, a genus botanically allied to *Cinchona*. *Remija* is said to be less particular than cinchona as to soil and climate, though the unsuccessful attempt to introduce it into Bengal does not bear out this inference. The Government very wisely and liberally distributed the whole crop of seed of *Cinchona* *Ledgeriana* gratuitously to applicants. We know that the boon of this free distribution has been much appreciated by planters all over India as well as in Ceylon. The percentage of febrifuge extracted from the bark treated in the factory was 273. This is stated to be a better result than that obtained last year, and is attributed to the superior quality of the bark used in the manufacture. The net result of the manufacture for the year was an outturn of ten thousand three hundred and sixty-three pounds of ordinary, and three hundred pounds of crystalline febrifuge. The cost price of febrifuge, which necessarily fluctuates from year to year, has in no former

years been so low as Rs. 8-8 a pound, and this is attributable to the larger percentage of the alkaloids extracted from the bark used in manufacture. We note that the year's working resulted in a profit of sixty-six thousand, two hundred and eighty-four rupees, which is equal to a dividend of six and-a-half per cent on the capital, a result which is very satisfactory and demonstrates the lucrativeness of Cinchona planting. Quinine ruled throughout the year at an average of ten shillings an ounce in London, which, fluctuating exchange at one shilling, eight pence per rupee is equal to rupees ninety-six per pound in India. The quantity of febrifuge supplied to Government Departments, during the year was four thousand, one hundred and eighty and-a-half pounds, and the cost was sixty eight thousand nine hundred and eighty-eight rupees. An equal quantity of Quinine at rupees ninety-six per pound would have cost four lacs, one thousand, three hundred and twenty-eight rupees. The saving to the State effected by substituting febrifuge of Government manufacture for English-made Quinine was therefore three lacs, thirty-two thousand, three hundred and forty rupees. If this be added to similar savings effected by the substitution of the febrifuge for Quinine in former years, the total saving to the State in the matter of Quinine amounts to above twenty-three lacs and twenty-five thousand rupees, and as the total cost of the plantations has only been ten lacs, the Government have good reason to be satisfied with the success of its Cinchona operations. Great attention had been given during the year to the improvement of the process of manufacture, and a better result was obtained than from any previous year. There is no doubt that by the adoption of a different and more costly process of manufacture, a still larger percentage of febrifuge might be obtained, but that the febrifuge so obtained would cost less per pound is, we are informed, doubtful. With a raw material which is cheap, bulky, and practically unlimited in supply, processes of manufacture which involve expensive carriage and apparatus are of doubtful advantage. The vexed question regarding the stripping *versus* the shaving systems is given by Dr. King in favour of the latter. However, we do not think that partial experiments like those inaugurated by Dr. King will carry much weight. Dr. King based his dictum on the first shaving of the trees, which yielded a very favourable result, but the opponents of the system declare that the bark deteriorates in an alarming manner after each harvesting of crop, where shaving has been adopted. Be this as it may, the Director speaks in unqualified praise of the Dutch process of harvesting the bark. This was introduced by Dr. Moens, the Director of Cinchona cultivation, to the Dutch Government, and consists in shaving off the greater part of the bark of a living tree to the height of from eight to ten feet from the ground, care being taken to leave everywhere a sufficiently thick layer of bark to cover the wood. This method is alleged to have had a fair trial, and the result has, it is stated, been highly favourable, as the bark renews perfectly. What, however, remained to be seen was whether the renewed bark was as rich in medicinal alkaloids as the original. It was with the object of determining this question that an analysis was undertaken during the year. This results are thus described by Doctor King: "The bark renewed rather slowly, but the analysis shows that it is very rich both in Quinine and Cinchonidine, and there can be no doubt that in countries where red bark trees are perfectly at home, and where their continuance in good health and vigor for a long series of years can be absolutely counted on, this shaving process is a very excellent one." In conclusion, we must remark on the excellent care and management bestowed on the plantations by Dr. King. They could not be in more perfect order, and the Doctor well merits the commendations and thanks uttered by the Lieutenant-Governor.

FORESTRY.

RUBBER CULTIVATION IN CEYLON.

ANOTHER clever contrivance has to be added to the long list of inventions by Ceylon planters for the more rapid, economical and successful performance of the work connected with the cultivation and preparation of new products which, of recent years, have excited so much attention. But first of all, it is satisfactory and re-assuring to find Ceara Rubber trees brought forward again as objects promising financial success for the cultivator. So much was said lately of the difficulty of collecting the milk—or rather watery substance—to make it pay, that on many sides

the cry was heard that Ceara Rubber trees were no good, and could not be made to pay, whatever might be the case with the other varieties. The Ceara trees to which the following experiments refer are growing on Peradeniya Estate from $3\frac{1}{2}$ to 4 years old, 28 to 38 feet in height, planted 12 feet by 12, and already with their branches so interlocked that there is dense shade beneath. Mr. Gilliat, the manager, has a strong opinion from the result of his observations and experiments that shade is inimical to the quality of the rubber got from the stem, and he would recommend planting 15 by 15 feet or even 20 by 20 as an experiment. Again, he has found that the best time to cut or tap is immediately after rain, and Dr. Trimen fully agrees that the flow of sap will be greatest just before the flowering season.

The great desiderata hitherto with all who have experimented with rubber trees in Ceylon have been a satisfactory, economical mode of tapping the tree without injuring it, of collecting the milk, and of securing it in a marketable form without the admixture of foreign substances or impurities of any kind. Mr. Dobree's knife was intended to be used for the removal (and replacement) of a portion of the bark—an operation which could scarcely be done without injuring the cambium. Mr. Wall tried skinning the tree, and then pricking it to induce the flow of the milk—a tedious and expensive process we should suppose. Certainly we have seen no instrument and heard of no means of tapping equal to that which Mr. Gilliat (the inventor) brought under our notice to-day. By his little instrument, with the accompanying tins and the process for the elimination of impurities, we are very hopeful Ceara Rubber cultivation may be made a very profitable branch of new products' industries in Ceylon, and we trust Mr. Gilliat's ingenuity and patient experimentalizing will meet with the reward they deserve. Suffice it to say that a cooly with this little knife can make the requisite number of cuts down the bark of the rubber trees with ease and rapidity without any material injury to the cambium. When made, the cut is about $\frac{1}{8}$ th of an inch open or wide by 1-16th inch deep; the cuts should not be nearer each other than nine inches—that is, trees on Peradeniya, four years old, 38 inches girth, take four horizontal cuts; but Mr. Gilliat is very hopeful (and Dr. Trimen we believe agrees) that after a month's interval, four more cuts in the intervals may be made without injuring the tree, so giving a second harvest of rubber. An ordinary cooly can go over 200 trees a day with 4 cuts in each, and a little podian can follow with the tiny tins (specially made by Mr. Gilliat out of empty kerosine tins) which are stuck into the tree to catch the exuding rubber. These tins can be made at 5 cents a piece. The most important part is however the chemical process by which all impurities are precipitated and lumps of pure white rubber, gradually assuming the pink colour on the edges so prized at home, are secured. Mr. Gilliat, being more or less of a chemist, had experimented for months over this, until he found the spirit, a very little of which dropped into the day's gathering of rubber, secures the above result. The elimination is secured even if 24 hours elapse between the tapping and the application of the spirit. Dr. Trimen is highly satisfied with the result; and we cannot help thinking that the beautifully white clean samples of rubber shown to us to-day will be priced as high as any in the home market. Mr. Gilliat is to lay them before the Planters Association. So far as his experiments have gone, from $\frac{1}{8}$ ths to $\frac{1}{4}$ ounce of rubber per tree is about the gathering or say $\frac{1}{8}$ th ounce from the two cuttings with a month's interval. No one can yet say how soon the tree will bear another harvesting. The experiment has to be made; but there is no reason to doubt a satisfactory profit from rubber cultivation, when harvesting and preparation are done with the instruments and according to the plan invented by Mr. Gilliat of Peradeniya estate, to whom all rubber planters owe, at least, their best thanks.—*Ceylon Observer*.

FOREST POLICY IN CEYLON.

MR. VINCENT in his report on Forest protection in Ceylon says:—In the various reports regarding Ceylon forests, and in consulting Government officials and others, there are two opposite opinions as to the future treatment of the forest question. One party thinks that forest devastation has already gone so far that no remedial measures can be of much use in saving the remaining forests; that so-called civilization having swallowed up all the forests in the vicinity of towns, and that as timber is so difficult and expensive to get from the remote forests still remaining, the latter should be left to the present management, and that for our future timber supply we should plant up with teak large areas contiguous to our towns. The opposite party would have the whole

of the forest area declared a reserve, all works of improvement—such as planting and thinning—abandoned, and all efforts concentrated on strict conservancy, which would be enforced by a stringent law protecting all Crown forest lands, not only from the chena cultivator, but excluding even village communities from the right of use in the adjacent jungles. Neither of these proposals appears to appreciate the true state of the case. To confine our attention entirely to planting would mean that the forests now left must gradually be absorbed by chena cultivation. We might then find out that teak would not grow, and certainly that its artificial growth would be most costly. On the other hand, to neglect all works of improvement, planting, thinning, &c., as at present, would mean that the forests must gradually deteriorate, and the supply of timber decrease. Past attempts at strict conservancy over the whole area have not been reassuring, and to be effective they would mean an enormous protective staff, costing more than the forests under the most favourable circumstances, could ever return. The true solution of the forest question is only to be found by combining strict conservancy over a limited area—assisted by works of improvement, planting, &c.—with general conservancy over the remainder of the Crown lands. Instead of attempting conservancy over the whole area, it is proposed to limit the sphere of our principal operations to the areas best suited for forming into reserved forests. With regard to the rest of the area, we shall only maintain a general conservancy, preventing the cutting of four or five of the most valuable trees; stopping also the clearing of forest and the unauthorized sale of forest produce, but, beyond this, giving villagers and other local residents as many privileges as they now enjoy. For their better protection it is also proposed, if necessary, to form certain areas into village forests for the benefit of village communities only.

MINERALOGY.

COAL AND IRON INDUSTRIES OF RUSSIA.

H. M. SECRETARY of Legation at St. Petersburg says that until the year 1850 the working of coal was almost entirely confined to the basin of the Don, and the output was only about 3,000,000 poods—the pood being equivalent to thirty-six English pounds—of anthracite yearly, the result of private enterprise. The coal-fields in the Ural, the Caucasus, and in the Island of Saghalien produced at the same time but 5,000,000 poods annually. As regards the situation of the various coal deposits, that in the Government of Moscow is considered the most useful taking into consideration the gradual destruction of the forests in Central Russia: that of the Don basin, by the ease with which it can be brought into connection, by means of railways, with the North of Russia, and especially with the Volga and Black Sea, furnishes the railways and steamers plying on the above mentioned river with a considerable supply of fuel. The coal deposits in the Ural Mountains are situated in the centre of a country rich in minerals of every sort, and their close proximity to the River Kama will admit of their being the source from which fuel will be drawn for the use of steamers on that river and on the Volga. In the centre of the beet-root sugar producing country about Kieff and Elizabethgrad, is another vein of coal; and there is also one in the centre of the great mineral deposits of those mountains. With the increase and improvement in railway communication, the output of coal has shown a marked increase. For 1868, the output of Russia—Poland excepted—was 12,000,000 poods; in 1870, 22,000,000 poods; in 1872, 48,000,000 poods; in 1874, 34,000,000 poods; in 1876, 83,000,000 poods, in 1879, 112,000,000 poods, and 1880, 122,000,000 poods. The chief obstacle to the more general use of coal throughout the empire is the excessive dearth of transport by rail, which frequently even surpasses the actual price of the coal. Of 2,700,000 poods of coal worked in the southern portion of the basin of the Don, the production suddenly ran up to 9,500,000 poods in 1872; but in 1874 it was reduced to 3,000,000 poods a year. Since the construction of the Kourak-Kharkoff-Azof Railway it has increased to such a degree that in 1879 it reached 47,000,000 poods. As regards anthracite on the eastern part of the basin, from 4,500,000 poods in 1863, it has increased to 10,600,000 poods in 1877, and in 1879 the total production of this basin was 70,500,000 poods, of which 20,500,000 was anthracite. In the Ural basin, the output of coal was from 1,500,000 poods in 1878 to 4,000,000 poods in 1879. The principal places worked at present are Louneff and

Korchoun-Lazareff. There are also in Asia vast deposits of coal, at Kouznetsk, in the Province of Tomsk. On the Kirgis Steppes, in the provinces of Semiplatinsk and Akmolinsk, about 1,000,000 poods are annually worked, chiefly at Karagandinsk. In Turkestan, coal is worked in the Kara-Tau mountains. In the province of Kuldja there are coal-mines worked by the Chinese with an output of 500,000 poods yearly. In Eastern Siberia, in the Island of Saghalien, a little coal is worked for the use of the fleet. In the province of Primorskaisa, on the Gulf of Poset, and on the Amoor, near the mouth of the Souyfon, the small amount of coal worked is for the use of the Siberian fleet. Coal was imported in 1880 to the extent of 83,500,000 poods from Great Britain, 21,500,000 poods from Germany, and 8,000,000 poods from Austria, besides smaller quantities from other countries. The iron industry is especially developed in the Ural mountains, chiefly in the Provinces of Perm, Orenburg, Oufa, Viatka, and Kazan. In the Ural, the principal mines are those of Blagodat, Wyssokaisa, and Magnitnaia. The mines of Blagodat contain from 52 to 53 per cent of iron, and about 57 per cent of cast iron is obtained; that of Wyssokaisa from 60 to 69 per cent of iron, and about 64 to 69 per cent of cast iron. The mines of Magnitnaia are the richest, containing 68 per cent, and above, of pure iron; but they are situated in a country devoid of fuel. According to official returns, in 1879, it was estimated that there were 1,926 beds of iron ore, 772 of which were worked, and produced 37,000,000 poods of mineral. Wyssokaisa-Gora had the greatest output, namely, 5,000,000 poods; and then Gora Blagodat with about 2,500,000; then follow the works of Kyshtym, Alapaleff, Kolounitsk, Slatavust, and Syterak, which furnish about 2,000,000 poods each. Throughout the whole of Russia, in 1880, 27,000,000 poods of cast iron were manufactured, of which 16,000,000 poods were made in the Ural. Of the total quantity of cast iron made in Russia, in 1880, 25,500,000 poods were made by using wood as fuel, and 1,500,000 poods with coal. The province of Perm heads the list as to the quantity of cast iron made, with 1,400,000 poods, then comes the province of Oufa with 2,000,000 poods, then Radoun in Poland with 1,500,000 poods. In 1880, 19,000,000 poods of steel were made, of which 2,000,000 in the Ural. It is a fact that the places where most steel is made are not those which produce the most iron. Thus the St. Petersburg Government in 1879 produced 7,000,000 poods of steel, and that of Orel in Central Russia 3,500,000 poods, then follow the two Polish Provinces of Warsaw and Piotrkoff, where 4,500,000 poods were made. The Province of Perm comes in as fifth, with hardly 1,500,000 poods.—*Journal of the Society of Arts.*

SERICULTURE.

TURKISH SILK FARMING.

A LATE number of the *British Trade Journal* contains an article entitled, "A Glance at a Turkish Industry," from which the following particulars are extracted:—Mr. Griffith has for many years been more or less engaged in the double task of combating the various diseases to which the silkworm is liable, and in trying to teach the peasantry how to regain something of the remunerative silk harvests which preceded the unfortunate year 1857. The loss suffered by Turkey when the various silkworm maladies first spread so violently is, he says, incalculable. He remembers the time when the wife of every gardener in the vicinity of Smyrna obtained from her crop of cocoons a sufficient return to enable her to pay for the clothing of her family for the whole year. In those days there were in the neighbourhood of Smyrna three large steam silk-reeling factories, where hundreds of women were employed, but when disease became general this industry had to be abandoned from lack of cocoons. *Fraxinaria* and *Pebrina* swept away the valuable indigenous races; large areas of mulberry trees were uprooted as being no longer required, and silk-farming came to be almost entirely relinquished. It is true that attempts were made to stem the tide of misfortune by the introduction of foreign eggs, but the peasantry, accustomed to handle their own large and beautiful cocoons, numbering 250 to the pound weight, became disheartened when they had to deal with the far inferior Japanese product of only half the size and weight. About this juncture Mr. Griffith obtained possession of a quantity of native grain, representing a peculiarly fine race of silkworms, but which were very much diseased. Being aware, from experi-

ence, that no batch of eggs is ever entirely contaminated by disease, and being a firm believer in the system of regeneration by isolation introduced some time before by the French physiologist, M. Pasteur, Mr. Griffith carried it into practice, hatching his worms in separate cells, and jealously following with the microscope every subsequent stage of their development. With an expenditure of infinite patience and trouble, he at length succeeded in rearing his present entirely healthy and vigorous brood, the eggs from which yield about 150 lbs. of cocoons for every ounce hatched; 12 lbs. of the cocoons, as taken fresh from the bushes, yielding 1 lb. of silk of the finest quality. Having thus accomplished his first and principal self-imposed task, Mr. Griffith set himself with equal ardour and determination to grapple with the second. It was not enough to be able to show the peasantry of Bourmabat, near Smyrna, where his chief magnaneries are situated, of Nymphiö, and of the island of Mitylene that he had mastered the dreaded *Pebrine* and *Flacherie*; but determined to leave no opening for misunderstanding or carelessness, he went among the people personally, with supplies of healthy eggs. In this manner he taught the farmers and peasantry the precautions they should observe, and secured their self-interested co-operation by making them partners in the season's venture. Even then he was occasionally baffled to some extent by the appearance of diseased moths bred from absolutely healthy *graine*, the result of infection caught from diseased worms still in the neighbourhood. Frustrated for the moment only, he still persevered, and now, after years of unremitting struggles with the enemy, he has restored to that district of Turkey some of the prosperity in silk-raising which it enjoyed thirty years ago. During the past season Mr. Griffith has scarcely lost a single worm through disease, and his peasant friends have been almost equally fortunate, although, others in the same localities, using French eggs, but without the advantage of a paternal director, have again lost heavily through the ravages of *Pebrine*. Accordingly, the most convincing proof that could be offered of the happy effect of Mr. Griffith's labours among the Turkish peasantry in the places alluded to appears in the following specimen cases of this year—a few instances out of many where educations of silkworms on the Pasteur cellular system have been attained without loss from eggs previously passed under the microscope:—Ellen raised 247½ lbs. of cocoons, which sold for 1s. 2d per lb., £14 8s. 9d.; she expended for mulberry leaves and a girl's help, £2 7s.; leaving a net profit of £12 1s. 2d. This peasant woman attended to the worms without aid during the first three ages, and was assisted by a girl throughout the last two. Adriana's crop consisted of 151½ lbs. of cocoons, from which she reeled 15 lbs. of raw silk, selling the same at 15s. per lb., £11 5s.; the cost of reeling, &c., was £1 2s., leaving a net profit of £10 3s. Possessing her own mulberry bushes, and having two young daughters, who assisted her during the last age, her outlay was small. Dhopinon and Costoula had a crop of 418 lbs. of cocoons, which produced 44 lbs. of raw silk, and sold at 15s. per lb., £33; the cost of reeling, &c., was £3 5s.; leaving a net profit of £29 15s. These two sisters were also the owners of a small mulberry garden, and were assisted during the last age by two daughters and a son. "Here," as Mr. Griffith points out, "are poor Turkish peasant women who have acquired, by a few days' labour, what would have taken their husbands three months to earn."

TEA.

THROUGH THE TEA DISTRICTS OF NORTH INDIA.

I.

DARJEELING.

THE lay of land in the Darjeeling hill-district, and the style of plant and of cultivation, is utterly different to that of Assam, and affords a more valuable basis for comparison with the Ceylon hill country. The soil at the top of the hills is mostly a very stiff clay, similar in appearance to much that we have in some parts of Ceylon, and exceedingly rich and fertile. Lower down, towards the valleys, the soil becomes quite different and consists generally of a rich black micaceous loam which is very free and porous. So stiff is the soil in parts near the ridges that it is almost impossible to walk along the roads without frequent falls, and ponies travel best if rough-shod.

Generally speaking, the estates are as steep as any planted land we have in Ceylon, but the style of cultivation is different to ours. In most cases, the hill-side at the commencement is formed into small level terraces, and a row of plants put along each; frequently, however, the land is lined in the usual way, up and down hill, is not drained, and yet the wash is trifling in the most heavy showers. The secret in this case is the tenacity of the soil, and the fact that hoeing is only done once or twice early in the season, to open it up, and that, after that, the weeds are only kept down by being out with sickles.

On terraced land, hoeing can be done more freely, but even here the weeds are generally cut and not dug over the faces of the terraces being carefully treated. Our system of draining does not appear to have been tried. It would, I think, be a success in stiff land, but in many places there is no tenacious subsoil to cut down into, and slips would be the only result of any attempt at draining. Tea is, however, generally opened on land which has been previously cultivated and abandoned by natives, and is consequently full of weed seed. To attempt to eradicate the weeds during their rapid growth in the rains would be most expensive, if not impracticable, and hence wash is to a great extent prevented by the thick matting of weeds which cover the ground and hold the soil together. In consequence of this system of cultivation, the appearance of the estates is not pleasing to the eye, the bushes being in many cases almost hidden by the growth of jungle. Strange to say, in spite of the numerous zigzag roads that have to be cut to open up the gardens, a road tracer is unknown in the district, and consequently, the gradients are very uneven and the roads generally steep and bad.

The buildings here are of a very different character to those in Assam, being *pukka* as a rule, and more like what we are accustomed to in Ceylon. There is a great dearth of machinery in the district, many large gardens having rolling machines only, and are still firing over stoves. Labour is very cheap, and where a manager is popular with his coolies, very plentiful. The labourers are all hillmen, Nepalese, Lepchas (the inhabitants of British Sikkim), and Bhootas. They are all under sirdars who receive their pay for them, and are recruited without any expense to the garden, small advances recoverable from the coolies' pay being alone given. The rate of pay varies from Rs. 3 to Rs. 5 a month, and hence Darjeeling has the great advantage of plentiful and cheap labour.

There is one drawback, however. It is the custom in many localities to give up a large portion of the waste land belonging to the estate to the coolies for the cultivation of Indian corn. In some valleys hundreds of acres of fine land are seen cultivated in this way, and the loss to the gardens is not apparent in any system of accounts, but none the less real and serious, must be very great. At the present time land fit for tea cannot be obtained in the neighbourhood of Darjeeling by any means, and hence the waste of good soil in the way just mentioned is the more deplorable.

Continuous crops of native produce are taken off the same soil by the coolies in hundreds of acres of land without the payment of any rent or the application of any manure; and the loss by exhaustion, wash, and introduction of weeds must be enormous. Not only this, but in a good (grain) year, the manager has frequently great difficulty in inducing his well-fed coolies to work at all, for they have no inducement to. As regards transport, the district is well served by the railway to its centre, though there are general complaints of delay in the transport of goods, which is excusable in view of the difficulties under which the line has been worked of late.

The hill labourers are very well accustomed to carry very heavy loads uphill, and it is wonderful to see the weight they can take up to the station. A maund chest, weighing perhaps 130 lbs. gross, is nothing to them, and I saw one man carrying a chest and-a-half, which cannot have been less than 170 or 180 lb.

The method of carrying is that which is, I believe, common to all hillmen—a strap is passed round the bottom of the load and over the forehead, which, with the back, supports the entire weight. The weight is thus distributed over the whole of the upper part of the body in a way which enables enormous loads to be carried up steep hills, which could not be taken for any distance on the flat by the method in vogue amongst Tamils. In appearance, as in character, the Lepchas, Nepalese and Bhootas are very different to the Bengalis. When well treated, they are a most cheerful, willing race, and make capital garden coolies. There is no labour law affecting them in Darjeeling, and the vexatious returns and espionage which prevail in Assam are here unknown. With no agreement, the coolies, if mismanaged, are given to leaving in a body, without any notice; but this is a very rare occurrence, their extensive plantations of Indian corn and other grain acting as a powerful inducement to them to settle in one spot. The British frontier being so very close, it says much for their honesty that cases of robbery and bolting are rare in the extreme, although it is the usual thing to send a few coolies and a sirdar alone to the station for cash, which they might easily make off with, if so inclined, with very small risk to themselves. The type of countenance of the Lepchas and Bhootas is decidedly Mongolian. The men are very ugly, though many of them have pleasing faces; a few of the women are nice-looking, but they are the exception. The latter have a custom of wearing their savings in rapeseed string together and fastened round the neck which would appear to offer opportunities for robbery, though such rarely if ever occurs. The Nepalese are by far the handsomest race of the three. They come from independent territory to the gardens, and take full advantage of the concessions which Government make to native settlers here as elsewhere.

Both in Assam and in Darjeeling the use of "cooty sacks" for plucking leaf is unknown. In the former district, the leaf is collected in baskets slung to the waist, and is weighed in twice a day in the latter: the baskets are supported on the back by forehead straps, and the leaf thrown into them over the shoulder, weighing-

in being generally done once a day only. Baskets are, undoubtedly, very awkward things to carry, especially among closely planted tea, and, when due care is exercised, that the leaf is not pressed down and allowed to heat in any way, the employment of bags is, I think, best, especially with coolies who are accustomed to pick coffee "cherry" in this way. As we all know, sour tea is the result when leaf is allowed to heat in the field, and, in using bags for its collection, the greatest care must be exercised that this does not occur and the *pressing down* of leaf be prevented.

There is one small matter in which Darjeeling is ahead of us and of Assam, and from which we might well take a lesson. The road to every garden is indicated where it leaves the main road by a sign-post giving the name of the estate. The great convenience of this system and the saving of the vexatious loss of time which sometimes occurs through losing one's way should be tried to be appreciated. A stranger travelling from the station has only to be put on the right road to start with, and he can scarcely fail to find his way with ease and without the loss of time, which "a coolie to show the road" means.

The coolies' lines are invariably situated high up in the hill-side, and never by any chance near the bottom of ravines. In spite of the elevation, it appears that fever hangs about persistently whenever there is the bed of a stream, and stagnant air. The same cause makes it desirable to have the factory in the hill-side, otherwise the distance between it and the bungalow and lines would be a great drawback. The difficulty and expense of choosing and clearing sites for buildings, with which we are familiar in some parts of Ceylon, is therefore reproduced in Darjeeling; but the most serious difficulty is that the supply of water-power can seldom be taken advantage of from the distance at which it is situated. The streams here have very little water in them during the dry season, at which time they are not required; our chief difficulty in Ceylon is that the dry season is the time when water-power is most necessary, and the minimum amount available during the dry months has to form the basis of our calculation in erecting tea machinery. The small extent to which water is used as a motive power in a hilly district like Darjeeling is indeed striking. In some cases, turbines are being used successfully, and there are a few water-wheels, but steam engines alone are employed in the large majority of factories. At one garden, I saw the most perfect piece of motive machinery I have seen in India: a very fine 30-foot water-wheel, perfectly erected, with no very large head of water, was employed driving the several rolling, sifting, and firing machines of a large factory, and it did so with perfect ease at a trifling cost compared with that of working the engine previously used. In another garden where a turbine was employed great difficulty was caused in the entrance into the machine during rainy weather of sand and grit, too small to be collected in the boxes. The most ingenious transmission of power is at a garden in the neighbourhood where a turbine at the river drives machinery in a factory some distance up the hill by a succession of driving belts and pulleys. There must be great loss of power by this system, and the wear and tear of belting would be considerable. As I have mentioned above, the factories are all permanent solid structures, and the limited area of the sites necessitates the utilization of all space inside them. Withering space is generally provided in an upper floor, and hastened by the heat from the stoves and firing machines below, where all machinery, &c., are situated. The remark about untidiness and want of cleanliness which, applied to Assam factories, would be out of place here, the Darjeeling buildings being, as a rule, kept clean and tidy, though not, I think, to the same extent as is frequently seen in Ceylon.

II.

KURSEONG.

THE tea gardens in the Darjeeling Terai, have not fulfilled the high expectations which were formed of them at their outset. With perfect lay of land, that as in Assam, and possessing all the advantages of unexhausted soil and a very forcing climate, they are disappointing in appearance and in result. The reason of this is very apparent. The land consists mostly of a rich surface soil, varying greatly in depth, but seldom approaching that of Assam, and below it lies a sub-soil of barren gravel and sand, excellent for drainage purposes, but ill-adapted for the support of a vigorous deep-feeding plant like tea.

During the early years of growth, the Terai gardens gave most satisfactory results, but when the plant is in full bearing, the yield in many cases falls off greatly, and the vigour of the bushes decreases.

The Doorga, a young and rising district to the east of the Darjeeling Terai, but similarly situated at the foot of the hills has a better soil and gives greater promise of success. The unhealthiness of these districts is proverbial, and has been against them from the first. On one garden I was at, 100 coolies had died quite recently from cholera and 200 had bolted in consequence, leaving an available force of 400 out of an original total of 700. Several instances have occurred quite recently of every soul leaving the gardens for a time, including managers and assistants—for their presence without coolies was of little use—in consequence of the numerous deaths from cholera. Fever is too common a complaint there to call for remark, and new-comers inevitably suffer from it in a greater or less degree for some time. Europeans after a time appear to become hardened and accustomed to it, and throw off attacks after but a temporary period of suffering; but the constitution must become undermined in time by these attacks, and it is a significant fact that in the Terai, in parts of Cachar too, I believe, and in many other localities, managers above 30 or 35 years of age

are a small minority. It is needless to point out the many ways in which this state of affairs affects the cost of production of tea. Apart from the risk of loss of labour during crop time—for the unhealthiest months coincide with the busiest crop season—the inducements to manager and assistants have to be made commensurate with the risks to life and health. In a copy of the *Observer*, which I came across by chance up here, mention was made of the fact that three planters had been engaged by a Calcutta firm for a term of years to work in tea gardens, the salaries were stated, and I think a remark was made that they appeared liberal, and that the gentlemen in question were fortunate in being offered them. I cannot but think that this remark was made without due weight being given to the conditions of life in an Indian up-country district. It must be remembered, first, that in the plains water is, as a rule, undrinkable even after the most careful filtering, whilst the cost of aerated waters—an absolute necessity—is very great when they have to be transported from Calcutta, as is usually the case. Servants, too, are a great tax on an assistant's income; "boys" to do the cooking and all the other work of a small bungalow are unknown and several servants must be kept, whose salaries, though individually not higher than what is generally paid in Ceylon, amount in the aggregate to a large sum. Fairly generous living and good cooking are essential to the preservation of health in a trying climate, and how impossible it is for these conditions to be fulfilled on the salaries mentioned I now know well. European managers and assistants are very highly paid on Indian tea gardens, and they thoroughly deserve the remuneration they receive. A young man from home on first joining gets, of course, a small salary of Rs. 150 a month and several allowances generally, and has to manage as he can on it; but good experienced men in charge of good gardens get from Rs. 500 to Rs. 700 a month and a commission on the profits, which sometimes ranges as high as 10 per cent in addition; in the smaller gardens Rs. 350 and Rs. 400 and commission are very generally given on the plains. The reason of this is that in order to live in such a way as to have a fair prospect of preserving his health a man must have an income of this kind, and must spend a considerable proportion of it. I cannot therefore agree that the sums offered the gentlemen in question, considering that they had experience of estate management and were accustomed to coolie labour, were specially liberal, and this opinion was endorsed by several Indian planters who had heard of the engagements. There are, of course, some parts of the plains more healthy than others, and it is to be hoped that they have been fortunate in the locality to which they were sent.

As is very generally known, most of the Darjeeling hill gardens, and some portion of those in the Terai, are planted with China tea. In Assam, on the other hand, a few gardens have China on them, but they are the exception. The opinion mentioned in a previous letter as having been given by a leading Calcutta tea-taster that a malty flavoured tea was only to be made from high-class indigenous plant, I have found to be quite erroneous. There is no question that at high elevations very choice flavoury teas are made from China leaf, many of them fetching the highest prices in the market; and in some situations, where the cold is great, hybrid plants do not yield in the same way as the hardy China bush. Extreme altitude apart, hybrid bushes are found to yield much more heavily in the hills than China, and the fact that the latter was so very extensively planted in the old days of tea-planting is very generally regarded as a misfortune. In appearance the tea from a China bush is, of course, far superior to any other. The proportion of pukes is very large, and there is not much coarse uneven leaf. The liquor has a very fine flavour, but not much strength. In some cases I was able to sample teas from China and hybrid bushes, grown on the same estate, and the latter was invariably the better tea of the two. The very high and cold portions of gardens apart, all new clearings are being planted with a good hardy hybrid.

The opinions expressed by planters as to the cause of the peculiar malty flavour, so much valued by brokers, possessed by some teas are varied and contradictory. In Calcutta, high-class plant and fine soil were given as the conditions, but many such teas have not got it, whilst in one case a tea from the rankest China had it in a marked degree. Another cause assigned was high-firing, but teas dried in a Gibbs and Barry's drier at a temperature of 700 had not got it. Blighted leaf, the stunted shoots from bushes suffering from "green fly" especially, was said to give a malty liquor by another, but I think this is questionable. A fourth planter of experience stated that by manipulation he could always produce teas of this character; a reference to the public sales of tea from his garden was conclusive proof against this statement. An instance was given me of a garden in the Terai, which for a few years, when young, produced fine malty teas fetching a high price, but afterwards they entirely lost this characteristic, and it seems most probable that some quality in the soil is the chief cause. There is an immense amount to be learned yet about tea manufacture, and this point is one which is not as yet understood.

In Assam and the Terai, in all low-lying districts in fact, the success of gardens is known to depend entirely on the class of plant put out. In the early days of planting anything was considered good enough, but now the very greatest care is taken in selecting seed, and the highest prices are paid for it. In the low country, seed from cultivated indigenous Assam trees is the best kind to plant. Seed from the original jungle trees is very delicate, and not so suitable for cultivation as the second generation. The lowest price at which such seed can be obtained is Rs. 150 (one hundred and fifty rupees) per manna, and much has been sold at Rs. 200. It is all bought locally, and in opening gardens in Assam and Cachar the first consideration is "how much seed can be afforded?" Then the acreage to be cleared is decided on.

There are two principal sources from which seed is obtained, the Towkoc and Singloo indigenous gardens, but all is booked for a long time to come locally at such prices as I have quoted. From

gardens which have not made a reputation as seed-producers, the very lowest figure at which high-class indigenous seed can be obtained is Rs. 120, and when a man shows you a nursery in which such seed is shown he does so apologetically, seed worth Rs. 150 per maund locally being the recognised kind suitable for the plains. In sampling teas from the ordinary hybrid and indigenous plant, the difference was as marked as that between China and hybrid in the hills, the indigenous giving a much stronger and more rasping liquor than the other. In yield, the advantage is even greater (in one garden the China gave two maunds, the hybrid 8 maunds per acre), and one of the finest sights I saw was a five-year old garden from Singloo seed with a heavy flush on it. When talking about seed to men in Assam, remarks were often made regarding the planting of cheap inferior seed sent to Ceylon, and cases were mentioned of seed picked anyhow from low class bushes to supply orders for seed at absurdly low rates. Plenty of good seed has gone to Ceylon of course, where fair prices have been paid, but with the large extensions in tea now going on in India itself, Ceylon men cannot expect to get good seed for an inadequate price. Noacacherry, the place from which Rookwood, New Forest, and some other places in Ceylon got their seed, is known as one of the best sources for hybrid seed of a high-class in Assam.

Indigenous Assam seed, though undoubtedly the right plant for the Ceylon low-country, is by no means suited for planting on the hills; a vigorous dark-leaved hybrid is much better, and such seed is more easily procurable, and at much lower rates. Almost all gardens in Assam are more or less mixed, a certain proportion of low-class plants being found everywhere, and in order to ensure that the manager or assistant shall personally overlook the seed-pickers and make them take it only from the good trees (a course followed in all gardens which go in for selling seed), a fair price must be paid. It is very evident, in fact, that good seed grown locally has in many cases been sold below its true market value as ruled by what such seed would fetch in India itself.—*Ceylon Observer*.

MR. ARMSTRONG ON TEA.

At a meeting of the Dkoya Planters Association, Mr. Armstrong read the following paper:—I have to thank you for inviting me to attend to-day, and am glad to give you my experience of the cultivation of tea in Ceylon, and I trust that the facts and figures, I shall have the pleasure to lay before you, will imbue not only yourselves in this district, but all of us, who have hitherto doubted—and we are now very few—with courage, to turn any unremunerative coffee fields we may possess into paying fields of tea, and in thus doing, I would still advise good bearing patches, which are to be found in every estate, to be kept as coffee, even if only aggregating 50 acres. 200 acres of tea will allow of this being kept in a high state of cultivation, without any increase in the labor force, as there are oftentimes when one is glad to have some other product that would employ one's labour, or a portion of it, for a few days, to the advantage of the tea. And the return from small patches of coffee worked in this way, are almost nett profit; or on the other hand, 5 acres even of tea may be worked to advantage with coffee. Do not let us, therefore, run into the other extreme, but let us keep all the coffee we can, where elevation and soil are suitable, and cultivate it highly with the aid tea will give us. Let our endeavour be to have as many products as our situation or elevation will allow us to grow. Bad fields of coffee we may have, but bad coffee estates, as a whole, I deny. As, at a meeting like this, time will not permit me to enter thoroughly into every detail connected with tea, I have endeavoured to curtail my remarks as much as possible. The more so, as your knowledge of coffee-planting will fill up any gaps. I consider our knowledge of coffee cultivation goes very far to aid us in that of tea, and, with our trained labor, most apt at picking up anything new, to aid us, we can place our tea in the market cheaper than any other tea-producing country in the world.

My remarks to-day have more especial reference to the cultivation of tea in what may be termed our coffee zone, in fact, to the practicability of tea taking the place, in some instances, of coffee, or of its being planted in forest land adjoining our coffee estates, and which we have thought too high for coffee.

Throughout this paper I refer to Assam-Hybrid tea only.

At what elevations will tea grow at in Ceylon to pay? From almost sea level to over 6,000 feet, provided soil and aspect are suitable.

SOIL.—Should be fairly good—the richer the better—deep and friable loam well mixed with sand; a shallow quartz soil is not good. Tea will not flush readily in this, although it may grow to a full-sized bush. A subsoil, well mixed with sand, or grit without showing a very good surface soil, will, although giving a slower growth at first, turn out a better paying soil, than one with a rich surface and clearly defined clayey subsoil without an admixture of sand; the more we pluck, the deeper the roots must go, and we must have room for them. The higher our elevation, the richer should our soil be, to make up for climate.

CLIMATE.—That that is best for coffee, will, I believe, for a *permanently*, be bound to be the best for tea. The beau ideal of a tea climate is Avilawella, Yatiyantota, and the lower portions of Morawakorale, also portions of Ambegamuwa; but they have not our coffee zone subsoil, as a whole; and our zone will, I think, make up, in its deeper soil, for the want of extreme heat, with moisture, which prevails in these districts, where, however, tea will rapidly make a fortune for its lucky proprietors.

The higher the elevation, the less rainfall is required, and *vice versa*; light showers alternating with sun, if we could order them so, would give us 1,000 lbs. an acre at 5,000 feet elevation. At the higher elevations, continued rain at the height of the monsoon has the same effect in checking the flush, for the time being, as a long continuance of sun has in the low country. Perhaps a good thing; for, with us, the bush has no wintering, and the only rest that of a 10 lb picking, instead of a 24 lb.

SITE AND LAY OF LAND.—Gently undulating land, for choice, is the best; but I have tea on steep land, doing as well as that on fairly flat undulating land. In fact, any land that is most suitable for coffee is most suitable for tea. In our new districts especially, we find our fields at the higher elevations making wood freely; but even at the best of times not giving much fruit, where we have coffee making most wood, there will our tea do best. In my experience I have had poor thin coffee pointed out to me as being suitable *only for tea*. I say no; if we are to expect tea to pay, we must not pick out our thinnest, weakest,—because washed coffee as being the most suitable site, but our free-growing leafy coffee, that from either a bad aspect with good soil (and we often see this), or from too high an elevation, has always persistently run to wood which we call leaf, in tea; with such coffee there need be no hesitation in at once planting it up with tea. Again, we have coffee that in the good old days has borne heavily, but that has now ceased to bear (temporarily or not, is beyond human ken) if we except occasional patches. *If the soil has not suffered from wash*, no matter what the coffee may have borne in the past, tea can take its place and flourish, as it has that in the soil to give it a start, and it can seek for nourishment far deeper than the coffee has ever reached. To sum up on this most important point, do not let us waste time and money on a coffee estate trying to grow tea, where we have found coffee will not make wood, though we may do so where our coffee, although now bad, has been good, in point of crop, provided the soil has not suffered from wash. Ridges and washed faces will be more profitably planted with aloes, which we may grow with other products with profit, or mana-grass to keep out the weeds, than with tea. These remarks do not apply to lower Ambegamuwa, Yakilessa, &c., where tea is *flourishing*, but where coffee could not exist, but to our true coffee districts.

Land at 4,000 feet to 5,500 feet that has failed in cinchona, provided soil and climate are suitable, will grow good tea. I have now tea 3½ years old on land that I planted up four times with cinchona (both *officinalis* and *succirubra*),—and that failed completely, although no expense was spared in the opening and planting of it,—doing as well as could be wished. Again, I have tea doing well on abandoned coffee land that was cleared and planted 7½ years ago with cinchona—which died out at 3 to 4 years. Elevation, in both instances, 5,000 feet and over. I have tea also doing well in land that was under cinchona for ten years.

Although tea does well, remarkably well, up to 5,000 feet in my own experience—and I have had figures shown me—proving that tea, at over 6,200 feet gave, at 4×4,400 lbs. per acre, at 6 years old, it does not follow that all and any land, at these elevations, will give the same results. The higher we go the better our soil must be. We must be rather dry than wet, not absolutely without rain for any length of time; but this we need not fear near our mountain tops; and the more shelter from the monsoon winds do we require. I will treat further down of the yield per acre from tea at the lowest to the highest elevations, and will now enter on seed, nurseries, opening and planting of tea, its cultivation, and manufacture.

SEED.—The greatest care must be taken to ascertain the seed you obtain is from the highest class hybrid, as with a poor *juv*, neither care in the manufacture nor cultivation can make a good liquoring tea, or give a profitable yield. Making allowances for poor plants, accidents, bad plants, and the having ample plants over for supplies, I calculate on one maund of 82 lb. for 6 acres planted 4×4, a maund of locally grown gives from 27,000 to 33,000 seed, according to the time that is allowed to elapse in weighing after husking; the sooner the seed is in the ground after gathering the better.

NURSERIES.—Choose the site as near a stream as possible, for the sake of water. Let the land be as flat as possible, make your beds 5 feet x 20 feet with 18-inch walks (which act as drains) between them. If you are going to plant out at six months from seed, sow your seed 2 inch apart every way. I find a very useful little tool for this is one I made many years ago for pricking out cinchona—a flat board, with handle on the top and pegs—50—underneath, any required distance apart, press the board, the pegs being underneath, on to your prepared bed, and you have it marked out in fifties to the distances apart, you wish to sow your seed. If you are going to plant them out at 1 to 2 years, 4 in. by 2 in., or, if space will admit, 4 in. by 4 in. apart sow 1½ inches deep, if no shade. If your plants are to be forced to save a season, manure your beds, sow in 2 by 2 in. apart and 1½ in. deep, shade with flat tate of jungle stuff 18 in. to 2 ft. above the bed, and water freely twice a day. You may begin to remove the shade by degrees, as soon as the wood at the collar of the plant hardens. Unless it is necessary for you to save the season, do not manure, nor pick out too good soil, as plants grown in better soil, than it is intended to plant them out in, suffer a check from their first start in the clearing. Give your nurseries time; do not dig your beds more than 6 in. to 9 in. deep, or the tap root, always unmanageable, will run deeper than ever. Every tea garden must keep up a nursery for supplies, which is a work we have to attend to every year. Stumps are best for supplies, and should be at the least two years old even up to four; a permanent nursery can be kept up in poor soil sown 3 in. by 3 in., and the strongest plants taken out for supplies.

LINING.—In fairly good soil, 4 feet by 4 feet is the best distance, in poorer soil 4 feet by 3 feet, on weak soil or exposed faces, 3 feet by 3 feet. It is as well to have 4 feet between the lines, as each line is almost a thoroughfare, from the number of times the pluckers have to move along it, as well as weeding contractors, in the course of the year, and the proper growth of the laterals is in a great measure stopped, if the pluckers have to force their way through too much; and in any ordinary fair soil, at a nearer distance than 4 feet between the lines, no light or air can get at the soil or through the bushes themselves, and they become towards the middle of the season an entangled mass of unhealthy wood. Therefore, although 4 by 4 does not suit the coffee lines in any way, if the tea is to be planted through it to eventually the extraction of the coffee (when tea is one year old), it is better to spend a little more money in lining, than to try and suit your lining to your coffee lined, presumably 6 feet by 6 feet.

HOLING.—If for plants at 6 months or 1 year from seed in coffee or in new land 9 in. by 9 in. will do well. If for stumps in coffee or new land 18 in. by 18 in. If seed or germinated seed is to be sown at stake, in coffee, loosen the soil with the ordinary fork; this is better than holing; as we are all aware, the coffee roots soon find their way into and fill a hole in which the good surface soil has been scraped, to the detriment of the seed: the same holds good with regard to manuring a young seedling which I have heard advocated in coffee.

PLANTS AND PLANTING.—The best plants are those at 6 months from seed, as they do not suffer the same check that a 1-year-old plant does, and equal it in growth at 12 months from planting out; have not such unmanageable tap roots, and stand sun better. Will do with shallower holes, cost less to plant, and have a better hold of the ground at 12 months. The best of all 2 to 4 years old stump-roots of which at this age are woody; will stand being broken; in fact cannot be raised from the nursery (which should be in poor soil) without breaking them. They should be stumped as with coffee at 6 inches, and have roots that will comfortably fit into an 18-inch hole, which they require. In fair soil a stump can be topped at 3 feet in a year, and regularly plucked at 18 months onwards, giving a fine spreading bush.

SEED IN SITU has its advocates. Its advantages are cheapness in sowing out, and the good hold it gets of the ground, an advantage in windy sites. Its disadvantages are, on any large scale, greater, first outlay in seed, as from two to three seeds are required at each stake, the liability of its being smothered (as a seed) by wash. Insect enemies, wooders (more especially among coffee), scraping off, unawares, the young shoot as it comes above ground, being trodden on by workers among coffee; many failures, therefore an extra cost in supplying, showing an uneven field; or again three seeds all coming up at one stake and the cost of removing two, but which of course come in useful for supplies. Also a great loss of growth for the first year in coffee by being shaded by it. If you have no insect enemies, notably the black grub, which nips off the young shoot just above the ground, and it is desired to sow in situ, germinate the seed first, and then one seed will suffice at each stake, and although great care must be taken in sowing, I have found that even if the root germ is broken or wounded, it throws out a bunch of rootlets and no harm happens.

STAKING.—This is not generally thought necessary. However I consider it most important; and wherever we have enough wind to have made it necessary to stake our coffee, it is there necessary to stake our tea, up to 2 years old certainly, and sometimes even up to 3 years of age—a stake driven straight through the middle of the bush without tying will do at 2 to 3 years; at 1 or 1½ years, it must be tied. Also tape is best for this.

TOPPING.—First topping should be done at from 15 months on aspects affected by the S.W. wind to 18 months—3 feet is the best height, or at lower elevations or on exposed ridges 2 feet 6

inch to even 2 feet. In topping the coolie has a stick of the desired height which he should place in the middle of the bush; the only care necessary is, to see he does not gather up a bunch of branches in his hand, to cut at one operation, but cuts each singly as it grows; the result will be a perfectly flat surface across the centre of the bush, with many young laterals round the bush untouched, which will soon reach the level to which we have topped; when they and the topped part begin to run up, all should be nipped back to the second leaf below the bud to keep as flat a surface as possible giving, say, at 6 months later, or at 1½ years of age, a bush with a fairly flat surface which will have reached 3 feet 6 inch to 4 feet in height. This very slight pluck after topping must be carefully done, only plucking those shoots that show an inclination to climb, so to speak; the plucking, with the topping, is necessary to force the lower laterals up, and keep your bush down and so form *surfaces*, otherwise, the bush will grow up somewhat in the shape of a poplar, and surface be lost for years. This plucking comes in useful in teaching your labour plucking and manufacture, and will eventually pay its cost in increased diameter of bush, and, therefore, increased yield.

PRUNING.—This is a most important work, and in Ceylon must not be too severe, yearly; more especially if your bushes are topped early. It should take place from June to August, in any part of Ceylon, perhaps July is the best month. There are three ways of pruning:—1st, with a flat surface; 2nd, saucer shape, i.e., hollowing out the centre; and 3rd, hooking down the bush. This last is murder, so I will pass it by without further remark. Saucer shape pruning does well for a time, but inclines to too matted a growth in the centre of the bush, which leads to too heavy a pruning yearly, more costly, and bad eventually for the bush. I have no doubt myself that pruning with a flat surface is best, so I will only treat of this mode.

When our branches after topping have reached up to say 3 feet 6 inch to 4 feet, having been kept down to this by plucking at 2 to 2½ years of age, according to whether the planting was done in the N.E. or S.W. (I am referring to tea at from 3,000 feet elevation upwards), they should be again cut to a level surface at 3 feet 3 inches, or if topped lower, as explained above, 3 inches above the topping. Any thin whippy branches trailing on the ground should be cut off close to the stems with a clean cut; and this is all for this year. Next pruning season when our bushes will be 3 to 3½ years old, they should be first topped to 3 feet or 2 feet 6 inches, according to elevation of garden, with a flat surface, all cross wood (i.e. branches growing through the bush), and all white barked whippy branches, wherever growing, should then be cut off with a clean cut close to the main stem or branch, and all growth encouraged outwards and upwards. No laterals should be cut back, except those growing into the bush which, as I have said, are to be entirely removed, but every branch should be topped or nipped back whether it has reached up to the limit of growth allowed, viz., 3 feet or 2 feet 6 inch, or not, thus we have given our bushes their first real pruning, and have got them into shape, which, with very little pruning they will keep for four years. Our procedure yearly for four years is then as follows always keeping a flat surface:—1st year, our bush being 4 to 4½ years old, top at 3 feet 3 inch; 2nd year, at 3 feet 6 inch; 3rd year, at 3 feet 9 inch; 4th year to between 3 feet 6 inch and 3 feet 9 inch; or if topped at 2 feet 6 inch, rising 3 inch yearly, keeping as much red wood as we can and removing each year thin white barked whippy branches, and cutting out all crows' feet from the surface, caused by plucking, leaving not more than a single fork on each branch at the surface; 5th year, cut down to 3 feet or 2 feet 6 inch at lower elevations or just below the original cut, and proceed as before. Thus low topping and heavy pruning is best done every 5th year. At our higher elevations, say from 3,500 feet upwards, we can top our bushes far higher than at the lower elevations, and so get increased surface; the bush does not run up from the bush, in the same manner it does lower down, our limit here, however, should be at the outside 3 feet 9 inch.

EXCEPTIONS.—Some bushes sulk, either from over-plucking or from bad wood, or from some other cause. These should have the knife applied freely either by being cut down to 18 inch, or by removing, with the aid of the same, one or two of the main stems in the centre, cutting down the outer growth as well, to 2 feet or 18 inches; the centre thus opened out will send up a new growth. These bushes should not be plucked till they are well up, say, to 4 feet, when they can be plucked and then topped with the knife to 3 feet.

PLUCKING.—This again is a most important work and requires close supervision. As a rule, plucking can be begun at 30 to 40 days after light pruning, I am speaking of coffee some tea, be it remembered—and should not be begun till the bud with opened leaf attached, and half the next leaf, can be plucked at one operation, leaving on one or sometimes two fully formed leaves to carry on the young shoot. The shoulder of the half leaf plucked remains on, and protects the eye at its base, which in its turn throws out a shoot. Shoots, according to elevation, will measure 6 inch to 9 inch long before the first plucking, after pruning, takes place. In after plucking, a good deal depends on the number of leaves on the shoot. If, with the bud and its partially opened leaf, we have four full leaves, then I should pluck at the second leaf down (leaving on the shoulder of this leaf, which protects its bud, and will probably give red leaf if removed) at one operation, and again half the 3rd leaf at another operation, leaving one fully formed young leaf on the shoot. Towards the end of the season, when the bushes are well up, I would act as above, only plucking at the 3rd leaf, leaving its shoulder on the stem, and thus removing at one operation a half leaf and the shoot consisting of two leaves and the bud. One simple rule in plucking is, to avoid having a bare shoot

DON'T DIS IN THE HOUSE.

"Rough on Rats" clears out rats, mice, beetles, roaches, bed-bugs, flies, ants, insects, moles, chipmunks, gophers.

B. S. Madon & Co., Bombay, General Agents.

with out a single leaf to help it on. As in most things, a practical lesson is best in plucking. As for the number of days in which it is necessary to go round the garden, I learn at a low elevation, it is considered necessary, according to the time of year, to get round in 7 to 10, up to 12 days at the longest. At high elevations, I have found in my best months, I should get round in 10 to 12 days to keep pace with my flush, and, again, in 15, to, in the very cold weather, December to January, 20 days. I do not think any hard-and-fast rule should be laid down, at any elevation; as to time, it is for the manager to watch his flush, and wait on it, just long enough, but no longer, and not to rush violently round his estate in a given number of days, which must lead to over-plucking, which means a reduction in yield sooner or later, although perhaps higher prices, for the time being; the benefit of this is also in a way nullified by a smaller outturn.

My average runs this season from, in my worst month, 10 lb. up to 20 lb. of leaf per coolie, including children. Some of my best pluckers have brought in from 36 to 47 lb. in ordinary months. I average from 20 to 24 lb. My plucking last season 1881-82 cost 5 3/8ths cents per lb. of tea. This season it will cost 8 cents. Leaf should be weighed in twice, daily, at mid-day and at knocking off time; it is best plucked into the ordinary cooty sack, and emptied into cane or bamboo baskets of the following dimensions, to avoid any chance of tight packing:—2 feet high, 18 inches across bottom by 1 foot across top. Cane baskets cost me 62 cents each; bamboo 25 cents to 37 cents, but cane are the cheapest in the long run, and nearer the cane country than I am would probably run from 37 to 50 cents each. Leaf must not be pressed down in either cooty sack or basket. Each basket is best kept by its owner in the line he is working in; the cooty sack should be repeatedly emptied into it, to avoid any risk of fermentation. As soon as weighing-in begins, leaf should be removed without delay to the withering shelves. Both baskets and cooty sacks should be taken in after the last delivery, or the coolie may use them to carry bazaar stuffs which may taint the leaf, and in any case they get smoked in his lines. *Bangy* tips, i.e., a hardening of the bud and stoppage of growth, should always be plucked; if the single leaf of which it consists is soft, it can be utilized, if not, it should be thrown away. It is as well to take the opportunity of any small plucking to rip off all bangy, the next eye will then nearly always throw out a free running shoot.

WITHERING.—The most simple and best shelves for this are formed of a framework of reapers, covered with sacking,—6 feet long and 3 feet 4 inches wide; the reapers forming this should be 2 1/2 inches wide by 1 inch thick; it takes 1 1/2 sacks to cover this, or jute-hessian forms a good cover. It is most convenient to have 12 of these shelves hanging, at 6 inches, one above the other. The reaper forming the front and back of the frame should project 1 1/2 inches; these projections are rounded off, and at the back a lot into holes cut in an upright post to fit them; in front the projections ends serve to hold up the shelves by fitting into knotted loops 6 inches apart in ropes, suspended from the roof. When it is desired to empty them, it is done by simply pulling out the ropes at each end, when the shelves hang flat down on their hinges, throwing their contents on the floor; the upper shelves are reached by the coolies who lay out the leaf to wither, by 3-legged stools 3 feet high. Leaf should be spread as thin as possible and turned over once during withering,—a shelf of above dimensions 6 feet x 3 feet 4 inches, holds very thinly spread 2 lb. of leaf, or at a pinch it will wither safely up to 4 lb., but not more. Say we put on 3 lb. in full plucking time, we require about 6 feet per lb. of leaf.

Leaf is properly withered, if, when held tight in the hand it does not crackle and keeps the shape into which you have pressed it; properly withered leaf is best told by touch, which experience gives us after a time. Leaf to give a good make, that is, twist and colour of infusion—copper colour—should be well withered, soft to the touch, not dry or crisp; under-withered leaf will not give a malty liquor, and the larger leaves (souchong) break in rolling, probably lessening the value of your broken pekoe, nor is the make so good as with well-withered leaf.

ROLLING.—Rather overdo this than under-roll; when leaf is properly rolled, it shows a good even twist, is very soft, and gummy to the touch; any liquor that exudes during the process of rolling should be mopped up by the leaf, now called *roll*. In hand-rolling it saves tip, if, when the rolling is half finished, the leaf is sifted through a No. 4, that which remains in the sieve is rolled separately, that which comes through *lightly* finished off. A man can take 2 lb. of withered leaf to roll at one time, and it takes him 20 minutes to finish it.

FERMENTATION.—After your leaf is sufficiently rolled, break up the roll well, so as to have no lumps in it and place it lightly in saucer-shaped baskets of bamboo, or cane 18 inches wide by 6 inches deep; these again to be placed inside a sack to ferment. Each basket holds about 12 lb. of roll—no actual time can be laid down for fermentation, as it all depends upon the day or time of year. In cold weather at 5,000 feet, I have waited for 6 1/2 hours for it to ferment, although my house has been kept at 90°. Again, at low elevations, I have seen roll properly fermented in 20 minutes from rolling. As far as time is concerned, at high elevations in ordinary weather, I find it takes from 1 1/2 to 3 hours. Machine-rolled ferments quicker than hand, an advantage in favor of machine. Roll is properly fermented when it shows at a first glance a bright new copper color. We must not in making this test, examine the roll too carefully as, if we do, we will find almost as many green as copper-colored leaves; the first glance on taking up a handful must decide us. As a rule, we should ferment up to our pekoe-souchong and let the rest take care of itself; if in doubt, underferment rather than overferment; overfermentation may cause the tea to be altogether sour, and in any case gives a dark-colored flat liquor, with darr dead-looking infusion.

For the first two or three rounds after pruning, our leaf will not give us a very bright infusion, and there is no use waiting on the fermentation to try and get it; all comes right as the wood matures.

Having arrived at a proper state of fermentation we should hand-roll lightly again, even if machinery is used. Coolies employed in the factory, firing, withering, &c., &c., are sufficient to do this. It is necessary, as it inclines the roll, opened more or less by fermentation, to take its twist again as it is being fired, and it also ensures the whole being thoroughly well separated, before being placed in the firing trays.

IN FIRING.—Over-charcoal the bottom of the tray which is covered with 24 to 26 brass mesh should be 21 inches from the fire grate which is again 9 inches above the level of the floor, or, the stoves are from the level of the floor to the top 30 inches high, 3 feet wide, at the top inside measurement, sloping to 1 foot 2 inches at the grate, which rests on ledges 1 inch wide, making below grate to floor level 1 foot wide. It takes 40 minutes to complete the firing of each tray of roll, as thus:—

Each tray 3 feet square inside measurement will hold 5 lb. of roll, which when fired equals about 2 lb. of tea. The tray should be constantly removed from the stove, and the contents well turned (on no account should any turning or fingerling be allowed when the tray is over the fire, as dust drops through, burns, and smokes the tea at once) after about 15 minutes drying, being constantly turned the while, the partially fired roll should be sifted through a No. 8 sieve; that, which remains in the sieve is again placed over the stoves, being as before constantly taken off and turned, and in 15 minutes is ready to be again sifted this time through a No. 6. It then takes 10 minutes to finish off, being constantly turned the while. The siftings are left on the table till all teas are finished firing: these represent broken teas, broken pekoe, pekoe No. 2, and dust; and are finished off over the hot stoves by the expiring fires—this takes about 10 minutes. Experience alone can tell us when teas are properly fired, they should feel crisp to the touch, and when bent resume their shape. As each tray is fired off, the tea should be put into a bin, for the purpose, and exposed on the table as little as possible.

TASTING.—The first thing the next morning as sorting begins, the "make" of the previous day or night should be infused and tasted carefully; we then know what to do with it, as we should keep our classes of different values (or grades) separately, and a good break may be spoiled by having one or two days inferior make mixed with it. Accidents sometimes happen also, such as overfermentation, if there is much night work, and this can only be detected by infusing the leaf; burning also. No tea should be packed away therefore (mixed with the bulk) till it is tasted and faults, if any, discovered, to be rectified in the future.

SORTING.—This is best done by women: one woman to every 100 lb. of tea. Red and large flat leaf is first picked out, and the tea is then passed through a No. 7 or 8 sieve, according to the size of leaf, i.e., tea of any particular day, that which comes through is next put into a No. 10 or 12—the higher the elevation the smaller and more wiry the make—that that remains in the No. 7 or 8 must be *lightly* broken through by hand; and what still remains in (very little) is congou and black fannings; that broken through is broken tea and broken souchong, which is mixed after removing the dust and broken tea with the pekoe souchong pure, remaining in No. 10 or 12, and the mixture classed as pekoe souchong. We then have left to deal with pekoe, broken pekoe, broken tea and dust, all of which has been passed through a No. 10 or 12—to extract as shown our pekoe souchong. This we again place in No. 10 or 12, *lightly* sifting it, to remove broken pekoe, broken tea and dust, leaving the pekoe in the sieve. We then with an ordinary rice winnow (the "shologoo"), remove broken tea and dust from the broken pekoe, the broken pekoe remaining in the winnow; the broken tea and dust we then put into No. 24, passing the dust through. To separate tea dust from pekoe dust, we can use either muslin or the winnow, again. We have now sorted our teas into the following classes:—1. Pekoe. 2. Pekoe souchong. 3. Congou (and fannings with large unrolled leaves). 4. Broken pekoe. 5. Broken tea; tea dust and pekoe dust. I do not count as a make nor yet fannings; the latter may, in most instances, unless the plucking has got ahead of you, be mixed, after breaking, with the broken tea. Fannings we break through a Reid's breaking machine, turning out a reddish make about twice the size of our broken tea, which, if poor in liquor, we ship separately as fannings; or if showing a fair liquor and not too much red leaf, mix with our broken tea. Of congou, fannings, and the dust, we have a very, very small percentage each day. The numbers of sieves we require are as follows:—No. 4 for sifting green leaf in rolling by hand, to give more "tips." No. 5 useful sometimes, when plucking has got ahead of you; and Nos. 6, 7, 8, 10, 12 and 24.

PACKING.—As, according to the new rules bulking on the gardens is now accepted in London and our tea saved from being all turned out, provided tares run pretty equal, I recommend each class of tea to be packed as soon as sufficient can be bulked to make 25 half chests of 50 lb. each. These should measure 15 x 16 x 16, and tare, on an average 18 lb. including lead, do not require hooping, and represent one coolie load. As soon as we have packed all our teas to complete that particular break or shipment, (which ought not to be under 5,000 lb. nett I think, and the more the better), we may add our dust, fannings, and congou which will only amount to a half chest or so of each. These teas will run from 5d. per lb. to 10d., and are as well shipped, if a half chest can be made up with each break from which they have been made. I find a half chest takes 3 1/2 lb. of lead and 1 1/2 oz. of solder—or cost of half

chest with lead-lining, &c., ready packed costs 3'500 per lb. of tea. Whilst on this subject, I think it would be of great advantage to us all if we could arrange to use one uniform package, and no package can be more convenient for us than the half chest as above—the majority of us have to transport our chests to the main road on coolies' heads—this half chest represents just a full coolie load. Whereas a chest takes two coolies to carry it, has to be hooped—a costly work—and there is all the worry of rope which is constantly stolen, and poles, to carry it; therefore, the saving in draft in London (under ½ a lb. of tea) and the slight difference in its favor in cost, in the first instance, is more than counter-balanced by the cost of hooping and transport, with the accessories of poles and rope. I trust, therefore, that those interested in tea in Ceylon, will from this year—our first great start almost—arrange to use one uniform package which shall be peculiar to Ceylon, and become known as the *Ceylon chest*. This for the bulk of our teas, but we may also pack occasional breaks in boxes; these should weigh under 28 lb. gross and thus save draft, say 10 to 15 lb. nett. And especially fine make could be shipped in these, forming a small break, and will often fetch fancy prices. Brokers at home accept both half chests and boxes, so there is no innovation here. A coolie can pack carefully, 15,—shall I call them Ceylon-chests?—in a day.

I now come to yield and cost per lb. f. o. b. at Colombo.

YIELD.—In my own experience, at 4,700 to 5,600 ft. elevation, with fair soil, ordinarily featured land, as our hill country goes, fairly steep, I find the yield has been as follows, and I do not consider I am yet in full bearing:—

At 2½ to 3½ years old 165 lb. tea per acre.

| | | | |
|----------|-----|---|---|
| 3½ to 4½ | 292 | " | " |
| 4½ to 5½ | 262 | " | " |
| 5½ to 6½ | 450 | " | " |

pruned heavily in July last season,—season ends in Sept.—to shape bushes which explains shortness of yield.

6½ to 7½ finishes end of Sept., 700 lb. per acre will be exceeded all round.

Bushes from the first have been under-plucked.

Again, I have yield given me at an elevation of 1,800 to 2,500 feet.

Average age 3 years 224 lb. per acre.

| | | |
|---|---------|---|
| 4 | 380 lb. | " |
| 5 | 315 lb. | " |

And please note, on this garden of over 200 acres in extent, there was a considerable loss of leaf, from allowing large areas to grow up during these three seasons, for seed, from which little if any leaf was plucked, had the full acreage been plucked the average would have reached 100 lb. more per acre.

Again, I have given me figures of an estate, at an average of 2,500 feet elevation, 400 lb. per acre at 3½ to 4½ years old.

Another estate, at an average of 500 feet, gives for the first six months of this year, January to June, being in June 4 years old, 400 lb. per acre, the estimate to December is 600 lb. per acre; and will probably be exceeded. Again, an estate from 100 to 400 feet, showing an average age all round of 4 years, gives 430 lb. per acre. This estate is wisely planted 5 × 6 and 3 × 5, and had it been 4 × 4 would have given a larger yield, as bushes do not cover the ground; but 430 lb. at 4 years is good enough, you will allow.

I have again many instances of estates, up to 3,000 feet, giving 400 to 600 per acre up to 5 years of age; and at 4,000 to 5,000 feet, from 380 to 420 lb. per acre.

We have all heard of Gallebadde and its 800 lbs. odd per acre; also of the older portion of Danodina with its 730 lb. per acre; a portion of one of my fields 3 acres in extent has given me at 7½ years 1,200 lb. per acre at 5,500 feet elevation, well sheltered with fine soil—an exceptional field, I will allow. These figures are fairly representative of tea in Ceylon at this date, and not one of the estates mentioned is in full bearing. What will the yield be when we are in full bearing, from 8 years of age upwards? We shall want lots of withering room, gentlemen: so be prepared in time.

Young as we are, and in the face of these yields at 6 years of age and upwards I feel perfectly safe in estimating an average yield of 400 lbs. per acre from tea in the coffee zone and above it, say from 2,500 to 5,700 ft. in sheltered situations, and in saying 5,700 ft. I do not wish it to be understood I draw the limit even here, but the figures I have had given me above this elevation, viz., at 6,300 ft., are only from a very small area under tea, which however gave at 6 years old 400 lb per acre at 4 by 4. For low-country teas, that is, teas at from 2,500 down to sea level, at 6 years old and upwards, I shall be very much surprised indeed if they do not show an average yield of 600 lb per acre. These estimates, gentlemen, may seem excessive, looking at the average yields from Assam and India generally, but compare our yield in this our very infancy with that in India, and you will find we can even now show an average, from estates at 3½ years old up to 6, which will more than double theirs. Inclemency of weather does not affect us in the same way in which it does our Indian fathers, as we have 11 months in which we pluck. If one month is too wet, we benefit all the more when the sun shines again, as we have lots of time if we have a spell of dry weather, on the other hand, this again is sure to be followed by rain, when we at once make up any loss.

Cost per lb. f. o. b.—I have to thank many friends for furnishing me with cost f. o. b. at Colombo, and choose the following

which are representative of all and may be relied on. In all cases, the tea was manufactured without the aid of machinery of any kind.

| | | |
|-----------------------|------------------|---|
| 450 lb. per acre cost | 36 cts. f. o. b. | Including cost of upkeep of young tea not in bearing. |
| 700 " " | 30 cts. f. o. b. | |
| 400 " " | 40 cts. f. o. b. | |
| 430 " " | 29 cts. f. o. b. | |

If we take the average of the above 4 estates, we have say 495 lb. per acre, hand-made, costing 34 cents f. o. b. at Colombo; London charges including freight are under 2½d.; but for all practical purposes let us say 2½d., the above teas at an average price of 1s. 2½d., and this is not a high average, leaves us 1s. nett, or at 1s. 8d. per rupee, 60 cents; a profit of 26 cents per lb. at 495 lb. per acre, say Rs. 128-70 profit per acre.

Whilst I am on the subject of yield I trust we in Ceylon will talk of lb. per acre and not manads; our tea is sold by the lb., what then can we have to do with manads?

With regard to plucking and manufacture, I find its actual cost is as follows without machinery:—

| | |
|--|--------|
| Plucking (including baskets and coolie sacks) ... cents | 7'000 |
| Withering, rolling, firing | 8'500 |
| Sorting, reffing, packing (in half-chests), including lead solder and chests | 4'000 |
| Total | 17'500 |

The rest of the works depend upon circumstances, and in many instances can be done cheaper with regard to some of the items than I now shew. Take, for example, a garden of 150 acres, bearing at 400 lb. per acre.

| | |
|---|-------|
| Supdt. including Factory Overseer, at R20 per acre, cost per lb. of tea | 5'000 |
| Weeding at 87 cents per acre, R10'44 per acre per annum | 2'610 |
| An ordinary pruning at R6 per acre | 1'500 |
| Nurseries, R225 | 375 |
| Supplying at R4'50 per acre | 1'125 |
| Roads and drains at R3 per acre | 750 |
| Tools say R150 | 250 |
| Transport Tea from estate f.o.b. | 2'200 |
| General Transport | 400 |
| House and tappal coolies, medicines, stationery, contingencies, and export duty and medical aid | 1'510 |
| Upkeep of buildings at R150 per annum | 750 |
| Manuring 30 acres per annum at R100—R3,000 | 5'000 |

| | |
|---|--------|
| Total estate expenditure per lb. | 21'500 |
| Add cost of plucking and manufacture as above | 17'500 |

| | |
|---|-----|
| Total cost 400 lb. per acre f.o.b. at per lb. tea hand made | 30 |
| Value of 400 lb. tea at 60 cents per lb. nett Rs. 240 | — |
| Less cost as above at 39 cents per lb | 153 |

Net profit per acre ... Rs4

Or if no manuring is done R104 per acre profit. Mindre of course eventually pays for itself by increased yield.

I believe the above to be a liberal estimate; it is at all events one higher than I should allow for the working of my own garden, which is in perfect order, R150 per acre for 400 lb tea is liberal enough, without machinery. I will now show my experience of the benefit machinery gives us.—On a coffee estate with water wheel already erected a Jackson's universal roller should be purchased, for even only 25 acres of tea, as I think the following figures will prove. I take 400 lb. of tea per diem as my standard as the following machinery works up to it, and this machinery is sufficient for a garden of 150 acres giving up to 800 lb per acre.

| | |
|---|----------|
| One Jackson's Universal Roller fixed ready for working | R. 1,200 |
| One Davidson's Sirocco | 1,300 |
| To drive the roller a 16 to 18 foot water-wheel will do, or if no water power a 2½ H P. engine costing say on estate | 1,500 |
| A second Sirocco is most useful and if means allow of it should be purchased, so I will add it, although not absolutely necessary | 1,300 |
| | 5,300 |
| Add a sorting machine at a cost of say | 950 |
| | R. 6,250 |

If the garden is to be increased in area it is better and cheaper to purchase at the first Jackson's larger roller called the "Eclairage" exactly the same as his "Universal" only working up to 8,000 lb. of leaf per diem, instead of 2,000 lb. and costing at the garden

"WELLS' ROUGH ON CORNS."

Ask for Wells' "Rough on Corns." Quick relief, complete permanent cure. Corns, warts, bunions.
B. S. Madon & Co., Bombay, General Agents.

SKINNY MEN.

"Wells' Health Renewer" restores health and vigor, cures Dyspepsia, Impotence, Debility. B. S. Madon & Co., Bombay, General Agents.

about Rs. 2,250. This with 4 Siroccos will work up to a 300 acre garden, and requires 5 H.P. to drive it.

Working, however, with our "Universal" at 400 lb. of leaf per diem, costs us as follows:—

| | |
|--|-----------|
| Plucking per lb. tea | cent 7-00 |
| Withering, rolling 1,000 lb. leaf = 400 lb. tea at 4 coolies, say | " 41 |
| Firing ditto at 3 coolies including firewood, say | " 25 |
| Sorting by hand, refiring, packing in half chests, including chests, &c. &c. | " 3-50 |
| Total cost of plucking, and manufacture by machinery | " 11-18 |

or a saving per lb. of tea of cents 8-34 as against hand-rolling and charcoal firing. I have not as yet worked a sorting machine, but I believe with two coolies to attend to it (driven by water or steam) a Jackson's or Ansell's will sort into four classes at the rate of 400 lb. per hour. Let us, for example, take 5 coolies per 1,000 lb. including the picking out of red leaf, its cost is exactly half that of hand-sorting or cents 0-165 as against cents 0-33 per lb., or say we have a saving of 84 cents per lb. of tea, with all machinery complete. This at 400 lb per acre yield represents a saving of Rs. 26 per acre or brings up profits as per former estimate to Rs. 100 per acre, or, if no manuring is done, on a young garden, to Rs. 130 per acre. From these figures you can work out the profits at any yield per acre; cost of manufacture is always the same, except when machinery is used, when the nearer we work up to its full power, the cheaper are we able to manufacture our teas, as there is then no loss in coolie labor at machinery; cost of the other works is increased or lessened in proportion as the yield is lower or higher. In further reference to machinery, in making any quantity of tea per diem the machine roller will turn out a better make than can be obtained by hand-rolling. One or two picked coolies might roll better; but when we have from 20 to 80 coolies to attend to, machine-rolled tea will carry off the palm. Sirocco-fired teas, as I have myself tested, are brisker and fuller than charcoal fired teas. I find my Sirocco at 275° will fire off 100 lb of roll per hour, equal to about 45 lb. of tea; my "Universal" rolls the equivalent of 200 lb. of green (unwithered) leaf per hour or 150 lb. of withered leaf in 75 minutes, taking in 37 lb. at a fill, which it rolls in 20 minutes, and we have to allow 5 minutes for emptying and refilling. If on a coffee estate you have not sufficient power already erected to drive the "Excelsior" roller (6 H.P.) I can, for *fine* leaf, recommend Kinmond's Centrifugal, one of which rollers I also have. This requires only the same power as the "Universal," but will roll off 4,000 lb. of green leaf per diem, instead of only 2,000; its cost is about Rs. 1,700 on the garden. It will not roll coarse leaf well, so with one of these rollers you must keep up with your flush, its great advantage is its cheapness as compared with the cross action for amount of work it does, with the small power it takes to work it (2½ H.P.) and with good leaf, the large amount of tip it turns out, although, where it can be worked, I prefer the large cross action (Jackson's) "Excelsior." To compare labour required to make 400 lb. of tea by hand and charcoal, with the number of coolies required to make the same with the "Universal" and "Sirocco," I find the following:—

| | |
|----------------------------------|------------|
| By hand-withering 1,000 lb. leaf | 2 coolies. |
| Rolling ditto | 40 |
| Firing and charcoal | 16 |
| Total for 400 lb. tea | 58 |

| | |
|-------------------------------------|------------|
| By machine-withering 1,000 lb. leaf | 2 coolies. |
| Rolling do. | 3 |
| Firing &c. | 3 |

Total ... 8

Saving in labour at 400 lb. of tea 50 coolies. This really represents a saving of 7½ cents per lb., or the roller saves 37 coolies and the "Sirocco" 13 coolies at 400 lb. tea. To aid in working the "Sirocco," I make any laborer not carrying in leaf, carry in a log of firewood every evening, which one coolie can cut up for the "Sirocco."

THE FACTORY—Should be roomy and have as much light as possible. All green leaf, whether withering or being rolled should be shut off from the firing, sorting, packing and store-room, or it collects dust, &c. Even with a "Sirocco," we should be provided with stoves, ready for charcoal firing, in case of accident. Cleanliness must prevail from rafter to floor. Our coffee stores, when too large for our crop, as at present, can be at a small expense turned into a suitable factory, a portion being walled off for our coffee crop.

Land can be opened, not including purchase of course, at the following rates per acre for the first year:—Jungle Rs. 80, patana Rs. 50, and coffee Rs. 40 to Rs. 50. Coffee should be uprooted when tea is at 1 to 1½ years old, unless it has on it sufficient crop to make it worth while leaving it. Tea at three years of age will prevent coffee giving sufficient crop to pay, and will eventually kill it out, so the two cannot be grown side by side. Coffee, when uprooted, may be stocked with advantage for firewood or charcoal. We can grow among our tea to advantage, according to elevation taking care not to overcrowd it, *C. officinalis* (best of all, as it gives no shade to speak of, and thrives better among tea than in the open), small-leaved Robusta and Ledger, the upkeep is nil, harvesting being the only expense after planting. We can grow with tea to a large saving of expenditure in both coffee or opium according to elevation. And let us aim, with tea as our mainstay, to grow all the products the elevation of our garden will allow of, with it. *Experientia docet.*—*Weekly Ceylon Observer.*

GOODALL'S Household Specialities.

A Single Trial solicited from those who have not yet tried these Splendid Preparations.

YORKSHIRE RELISH.

The Most Delicious Sauce in the World.

This cheap and excellent Sauce makes the plainest viands palatable, and the daintiest dishes more delicious. With Chops, Steaks, Fish, &c., it is incomparable. In bottles, at 6d., 1s., and 2s. each.

GOODALL'S BAKING POWDER.

The Best in the World.

Makes delicious pudding without eggs, pastry without butter, and beautiful light bread without yeast. In 1d. packets, 6d., 1s., 2s., and 5s. tins.

GOODALL'S QUININE WINE.

The Best and most Agreeable Tonic yet introduced.

The best remedy known for Indigestion, Loss of Appetite, General Debility, &c. Restores delicate individuals to health. At 1s. 1½d. and 2s. 3d. each bottle.

GOODALL'S CUSTARD POWDER.

For making Delicious Custards without Eggs, in less time and at half the price.

The Proprietors can recommend it to Housekeepers generally as a useful agent in the preparation of a good custard. **GET IT A TRIAL.** Sold in boxes, 6d. and 1s. each.

GOODALL'S GINGER BEER POWDER

Makes Three Gallons of the Best Ginger Beer in the World for Threepence.

The most valuable preparation for the production of a delicious and invigorating beverage. It is easily made, and is by far the cheapest and best Ginger Beer ever offered to the public. Sold in packets, 3d. and 6d. each.

GOODALL'S EGG POWDER.

Its action in Cakes, Puddings, &c., &c., resembles that of the egg in every particular. One penny packet will go as far as four eggs and one sixpenny tin as far as twenty-eight. Sold everywhere, in 1d. packets; 6d. and 1s. tins.

GOODALL'S BLANCMANGE POWDER

Makes delicious Blancmange in a few minutes. In boxes at 6d. and 1s. each.

All the above-named Preparations may be had of all Grocers, Chemists, Patent Medicine Dealers, and Oilmen.

Proprietors: GOODALL, BACKHOUSE & CO, Leeds, England.

FREEMAN'S SYRUP OF PHOSPHORUS.

Nature's Great Brain and Nerve Tonic and the most wonderful Blood Purifier. The highest Medical Authorities say that it is the only Cure for Wasting Diseases, Mental Depression, Loss of Energy, and Stomach Complaints.

It is pleasant to the taste, and might be taken by the most delicately constituted. In the most enfeebled it builds up a NEW AND HEALTHY CONSTITUTION. One dose of this Remedy is equal to Twenty Doses of Cod-Liver Oil.

Thousands have been snatched from the brink of the grave by the timely use of FREEMAN'S SYRUP OF PHOSPHORUS. May be had of all Chemists and Patent Medicine Vendors, in bottles at 2s. 9d., 4s. 6d., 11s., and 33s.

SPECIAL AGENTS:

GOODALL, BACKHOUSE & CO.,

ZULULAND AND CETEWAYO.

"I know what it is," he answered; "this honey is made from euphorbia flowers, which are very poisonous." This explanation made me feel exceedingly uncomfortable; but I elicited from him that there was not much danger, as the 'masses' taken with it would neutralise the effect of the poison. Directly he mentioned poison I dived into the packs, and pulled out a bottle of ENO'S FRUIT SALT, and emptying a quantity into two pannikins, filled them up with water, and several times repeating the dose, in a few hours we were considerably better."—*"Zululand and Cetewayo," (p. 138), by Captain W. R. Ludlow, 1st Batt. R. V. Royal Warwickshire Regiment.*

"What on earth shall I take to Zululand?" asked my friend Jim Law one day at Aldershot, when he had just received orders for South Africa, to start at forty-eight hours' notice. I replied, 'If you take my advice—and it's that of an old traveller—you'll not budge without a few bottles of ENO, even if you leave half your kit behind. I never am without these Salts, and, please the pigs, never intend to be.' On his return I inquired, 'Well, how about ENO'S FRUIT SALT?' 'My dear fellow, it was the best advice you ever gave; they saved me many an illness; and when I left Tuegla, I sold the remaining bottles for ten times the original price!'—*Lieut.-Col.*

JEOPARDY OF LIFE. THE GREAT DANGER OF DELAY.

You can change the trickling stream, but not the raging torrent.

WHAT EVERYBODY SHOULD READ.—How important it is to every individual to have at hand some simple, effective, and palatable remedy, such as ENO'S FRUIT SALT, to check disease at the outset! For this is the time. With very little trouble you can change the course of the trickling mountain stream, but not the rolling river. It will defy all your tiny efforts. I feel I cannot sufficiently impress this important information upon all Householders, or Ship Captains, or Europeans generally, who are visiting or residing in any hot or foreign climate. Whenever a change is contemplated, likely to disturb the condition of health, let ENO'S FRUIT SALT be your companion; for, under any circumstances, its use is beneficial and never can do harm. When you feel out of sorts, yet unable to say why, frequently without any warning you are suddenly seized with lassitude, disinclination for bodily or mental exertion, loss of appetite, sickness, pain in the forehead, dull aching of back and limbs, coldness of the surface, and often shivering, &c., &c.; then your whole body is out of order, the spirit of danger has been kindled, but you do not know where it may end: it is a real necessity to have a simple remedy at hand that will answer the very best end, with a positive assurance of doing good in every case and in no case any harm. The pilot can so steer and direct as to bring the ship into safety, but he cannot quell the raging storm. The common idea when not feeling well is, "I will wait and see, perhaps I shall be better to-morrow;" whereas, had a supply of ENO'S FRUIT SALT been at hand, and use made of it at the onset, all calamitous results might have been avoided. What dashes to the earth so many hopes, breaks so many sweet alliances, blasts so many auspicious enterprises, as untimely death?

ENO'S FRUIT SALT.—After suffering for nearly two and a half years from severe headache and disordered stomach, and after trying almost everything and spending much money without finding any benefit, I was recommended by a friend to try ENO'S FRUIT SALT, and before I had finished one bottle I found it doing me a great deal of good, and now I am restored to my usual health; and others I know that have tried it have not enjoyed such good health for years.—Yours most truly, ROBT. HUMPHREY, Post Office, Barrasford.

SUCCESS IN LIFE.—A new invention is brought before the public, and commands success. A score of abominable imitations are immediately introduced by the unscrupulous who, in copying the original closely enough to deceive the public, and yet not so exactly as to infringe upon legal rights, exercise an ingenuity that, employed in an original channel, could not fail to secure reputation and profit.—ADAMS.

CAUTION.—Legal rights are protected in every civilised country. Examine each Bottle, and see the capsule is marked "ENO'S FRUIT SALT." Without it you have been imposed on by worthless imitations. Sold by all Chemists, price 2s. 9d. and 4s. 6d.

THE ART OF CONQUEST IS LOST WITHOUT THE ART OF EATING.—DINNER ENGAGEMENTS.—STIMULANTS.—TOO HIGH FOOD.—LATE HOURS.—INSUFFICIENT EXERCISE.—EXCITEMENT.—A gentleman writes: "When I feel out of sorts, I take a dose of ENO'S FRUIT SALT one hour before dinner or first thing in the morning. The effect is all I could wish." How to enjoy good food that would otherwise cause biliousness, headache, or disordered stomach—use ENO'S FRUIT SALT.

DIRECTIONS IN SIXTEEN LANGUAGES HOW TO PREVENT DISEASE.

Prepared only at ENO'S FRUIT SALT WORKS, HATCHAM, LONDON, S.E., by J. C. ENO'S Patent.

PHOENIX IRON WORKS, CALCUTTA.

THE OLDEST ENGINEERING ESTABLISHMENT IN INDIA,

Metal Merchants, &c.

*Forged and Cast Iron Work, Boilers, Machinery for Jute, Cotton and Rice Mills, Collieries, Indigo Concerns, Tea Gardens, &c.,
Contractors' and Brick-making Plant, and every class of Iron and Brass Work made to order.*

SOLE AGENTS FOR

Robey & Co's celebrated Portable and Fixed Engines and Machinery, Gwynne & Co's "Invincible" Centrifugal Pumps, Gould's Rotary Pumps, and Robinson's Patent Steam Traps.

IMPORTERS AND MANUFACTURERS OF EVERY DESCRIPTION OF STEAM ENGINES AND MACHINERY.

Robey & Co's Portable, Horizontal, Fixed, and Patent "Robey" Semi-fixed Engines, Combined Vertical Engines and Boilers, Land and Marine Boilers, Gould's Rotary Power Pumps, J. & H. Gwynne's "Invincible" Centrifugal Pumps, Hand, Lift and Force Pumps, Tangye's "Special" Steam Pumps, "Vauxhall" Donkey Pumps, Flour Mills, Saw Benches, Spencer's Hand Drilling Machines, Steam Pressure Recorders, Richards' Engine Indicator, Gifford's Injectors, Cooking Stoves, Fire-Proof Safes.

J. & H. Gwynne's "Invincible" Centrifugal Pump.

This Pump being arranged to swivel on the bed-plate may be fixed at any angle required. It does not require a foot-valve, being fitted with small air exhauster and clack on discharge, which always keep it charged ready for work.

Robey's Combined Vertical Engine and Boiler.

This class of Engine is nearly twice as large as those of the same nominal horse-power of some makers. The Engine, instead of being fixed to the Boiler as is usual in Engines of the same class, is erected on a massive Cast Iron Standard which makes it quite independent of the Boiler.

Ransome's "Indian" Plough, price—Rs. 15.

These Ploughs have been expressly designed and manufactured for the use of the Ryots of India, whose special needs have been carefully studied in their construction. They embody all the qualifications for which the native-made implements have hitherto been preferred, whilst being incomparably superior in strength, durability, and efficiency.

MORAE'S PATENT SUB-SOIL AND GENERAL PLOUGH

Turns up the soil to three times the depth of a native plough, and leaves the good mould on the top. Goes through the dirtiest land without getting choked with weeds. Price, Rs. 15.

INDIGO AND TEA PLANTERS' IMPLEMENTS AND STORES.

ENGINEERS' TOOLS AND STORES OF ALL KINDS.

ALWAYS ON HAND A LARGE STOCK OF PLATE, BAR, ANGLE, TEE AND CORRUGATED IRON, STEEL, BRASS, COPPER, PIG IRON, FOUNDRY COKE, SMITHY COAL, FIRE BRICKS, AND FIRE CLAY.

BLAKE'S PATENT DIRECT-ACTING STEAM-PUMP,—MORE THAN 10,000 IN USE.

THE FOLLOWING ARE SOME OF THE PROMINENT ADVANTAGES OF THE BLAKE PUMP:—

It will start at any point of stroke.

It has no dead point.

It works fast or slow with the same certainty of action.

It is economical. Has a lead on the Slide Valve.

It is compact and durable.

Hand Power Lever Detached.

It is interchangeable in all its working parts.

It will deliver more water than any other Pump.

It is made of best materials in the most workman-like manner.

Can be worked at 200 strokes per hour, or 20 strokes per minute.

BLAKE'S PATENT
Direct-Acting Steam Pump and Boiler Feeder.

COMPLETE OIL MILL.
Oil Mills, for Steam or Cattle Power.

Double-barrel Contraction Pump, for Hand or Steam Power.

Double-barrel Fire Engine, for Maudslows, Factories, &c.

Deep-well Pump for Hand Power.

Fire Engines, for Tunnels, Railway Stations, &c.

Force Pump for Barrow.

Worm-driven Portable Pump.

Patent Centrifugal Pump, for Contractors use, or Irrigation Work.

Cast-iron House or Garden Pump.

Portable Irrigator for Hops or Steam Power.

Deep-well Pumps, for Horse or Bullock Power.

Vertical Combined Steam Engine, Boiler, and Deep-well Pumps.

Double-barrel Force Pump in Frame.

Improved Steam Boring Apparatus, also

Boring Tools of every description, for Artesian Wells, testing for Minerals, Foundations, &c.

BLAKE'S PATENT DIRECT-ACTING STEAM PUMP AND VERTICAL BOILER

OVER 450,000 FEET SOLD DURING 1881.

* Including 3,877 feet of main Driving Belts, of widths ranging from 13 in. to 60 in., are working in over 6,000 Mills and Works in Europe and America.

The following Tests (by Kirkaldy, of London) show the relative strength and value compared with Leather.

| | Breaking Strain per Square Inch of Section. | Price per foot. |
|--|---|-----------------|
| Best Double Leather 6 in. Belting | 3,572 lbs. | 5s. 7d. |
| Gandy's 6 in. x 3-ply Cotton | 6,341 lbs. | 2s. 6d. |

THE GANDY BELT.

**Any Length or Width
for Main Driving.**

It is the best belt ever made for all purposes. Much Cheaper and Stronger than Leather. Thoroughly Waterproof, and not affected by temperature, clings well to the pulleys, runs true, and can be made any length without joints.

This Series of Belting (see engraving) was supplied in One Order to Messrs. John Crossley and Sons, Halifax, May 1, 1880, and continues to give entire satisfaction.

THE "GANDY" BELT

GANDY'S Patent American Cotton Belting can claim a superiority over leather belts in every particular; its cost being about half that of leather, while its strength and gripping power is about double that of the best leather, as shown by repeated tests taken by Kilkenny, of London. These tests are given above to which special attention is directed. These "Gandy" belts are made of any width up to 72 inches, and any length up to 340 feet without a joint, thus obviating the necessity of having two belts on the same pulley, a system of driving which is never satisfactory as it is impossible to have belts of exactly the same tension; hence one or the other is always causing a stoppage. These stoppages are avoided by using Gandy's Patent Belting one width. These Gandy Belts are made of the finest American Cotton Duck, specially prepared at Baltimore for the purpose, and then put together and finished by Gandy's patented special Machinery and process to prevent stretching, and render them impervious to atmospheric influence. Objections of a nature such as these, the universal adoption of Gandy's Belts can only be a question of time.

A SUBSTANTIAL GUARANTEE GIVEN WITH EVERY MAIN DRIVING BELT.

MAURICE GANDY.

U.S.A.

THE GREAT REMEDY FOR PRICKLY HEAT, INDIGESTION, HEADACHE, BILIOUSNESS, AND FEVERS.

LAMPLOUGH'S PYRETIC SALINE.

As possessing elements most essential for the restoration and maintenance of health with perfect vigour of body and mind. It is **Invigorating and Tasteless**, forming a most **Invigorating, Nutritious, and Refreshing Beverage**. Gives instant relief in **HEADACHE, BRUISES, RHEUMATISM, CONSTIPATION, INDIGESTION, LAMITUDE, BRUISES, AND FEVERISH COLDS**; prevents and quickly cures the worst forms of **TYPHUS, SCARLET, JUNCLE, and other FEVERS, SMALLPOX, MEASLES, and ERUPTIVE or RASH COMPLAINTS**, and various other altered conditions of the blood.

Dr. FROST—“Unfolding germs of immense benefit to mankind.”
Dr. MORGAN—“It furnishes the blood with its lost saline constituents.”
GOVERNMENT OFFICIALS AND PLANTERS caring for the welfare of their employes should note its value as a specific in Fever cases.

Dr. J. W. DOWLING—“I used it in the treatment of forty-two cases of Yellow Fever, and am happy to state I never lost a single case.”
Dr. W. H. HARRIS—“Since its introduction the Fatal West India Fever are deprived of their lethality.”
Dr. H. B. BENTLEY—“Representative of the GOVERNMENT OF SINGAPORE, in a letter of request for analytical analysis of the Pyretic Saline, observes: ‘It is of great value, and I shall rejoice to hear it is in the houses of all Europeans visiting the tropics.’”

To be obtained of any Chemist or Drug Store, in Patent Glass-stoppered Bottles, 2s. 6d., 4s. 6d., 11s., and 21s. each. Please note in connection with the recently observed effects of the use of Climate and other preparations of Magnesia that **LAMPLOUGH'S PYRETIC SALINE** is warranted not to contain any substance which would cause calomelous or other earthy deposits.

PHOENIX IRON WORKS, CALCUTTA.

THE OLDEST ENGINEERING ESTABLISHMENT IN INDIA,
JESSOP & CO.,

Civil and Mechanical Engineers, Contractors, Brass and Iron Founders,
Metal Merchants, &c.

*Forged and Cast Iron Work, Boilers, Machinery for Jute, Cotton and Rice Mills, Collieries, Indigo Concerns, Tea Gardens, &c.,
Contractors' and Brick-making Plant, and every class of Iron and Brass Work made to order.*

SOLE AGENTS FOR

Robey & Co's celebrated Portable and Fixed Engines and Machinery, Gwynne & Co's "Invincible" Centrifugal Pumps, Gould's Rotary Pumps, and Robinson's Patent Steam Traps.

IMPORTERS AND MANUFACTURERS OF EVERY DESCRIPTION OF STEAM ENGINES AND MACHINERY.

Robey & Co's Portable, Horizontal, Fixed, and Patent "Robey" Semi-fixed Engines, Combined Vertical Engines and Boilers, Land and Marine Boilers, Gould's Rotary Power Pumps, J. & H. Gwynne's "Invincible" Centrifugal Pumps, Hand, Lift and Force Pumps, Tangye's "Special" Steam Pumps, "Vauxhall" Donkey Pumps, Flour Mills, Saw Benches, Spencer's Hand Drilling Machines, Steam Pressure Recorders, Richards' Engine Indicator, Gifford's Injectors, Cooking Stoves, Fire-Proof Safes.

J. & H. Gwynne's "Invincible" Centrifugal Pump.
This Pump being arranged to swivel on the bed-plate may be fixed at any angle required. It does not require a foot-valve, being fitted with small air exhauster and clack on discharge, which always keep it charged ready for work.

Robey's Combined Vertical Engine and Boiler.
This class of Engine is nearly twice as large as those of the same nominal horse-power of some makers. The Engine, instead of being fixed to the Boiler as is usual in Engines of the same class, is erected on a massive Cast Iron Standard which makes it quite independent of the Boiler.

Ransome's "Indian" Plough, price—Rs. 15.
These Ploughs have been expressly designed and manufactured for the use of the Ryots of India, whose special needs have been carefully studied in their construction. They embody all the qualifications for which the native-made implements have hitherto been preferred, whilst being incomparably superior in strength, durability, and efficiency.

Howard's Ryot's Plough, No. 6, price—Rs. 20.

MORAE'S PATENT SUB-SOIL AND GENERAL PLOUGH
Stirs up the soil to three times the depth of a native plough, and leaves the good mould on the top. Goes through the dirtiest land without getting choked with weeds. Price, Rs. 15.

INDIGO AND TEA PLANTERS' IMPLEMENTS AND STORES.
ENGINEERS' TOOLS AND STORES OF ALL KINDS.
ALWAYS ON HAND A LARGE STOCK OF PLATE, BAR, ANGLE, TEE AND CORRUGATED IRON, STEEL, BRASS, COPPER, PIG IRON, FOUNDRY COKE, SMITTY COAL, FIRE BRICKS, AND FIRE CLAY.

Catalogues on Application.

KAING GRASS FOR PAPER-MAKING.

(To the Editor of the Paper Makers' Monthly Journal.)

SIR,—Many of my friends, knowing that I hold a commission from the Indian Government for the collection and production of "paper stock" from bamboo and other fibres in British Burmah, have asked me how it was I had allowed Kaing grass to escape my attention.

Mr. Buckle's communication, published in the August number of the Journal, shews ample reason for this assumed neglect on my part.

In 1878 the Indian Government sent me a consignment of this elephant or tiger grass (as it is called), requesting me to investigate its value for paper, and report thereon. This I did, stating that, in my judgment, although possibly it might be utilised in India locally, for a low class or quality of paper, the yield would be so small of available fibre, and the cost of reducing it to a carrying condition so heavy, that it could not possibly be imported into this country to pay.

A simple analysis of Mr. Buckle's figures fully endorses this, my opinion. These shew that "47,136 pounds of the grass as cut produced" 8,761 pounds of raw stock, "a yield or result of 14 per cent only after cleansing, and further that the cost of the raw grass and the labor in producing the raw stock amounted to 17s. 1d. for 100 pounds, or equal to £19 per ton.

The freight alone of such raw stock to Europe, owing to its bulky character, would amount to more than the present selling price of esparto grass, but I must assume that Mr. Buckle could never contemplate shipping this raw stock to England; therefore, that it would be chemically treated and converted into a tow-like condition to economise transit, charges, and freight.

This operation would have to be conducted in the ordinary manner as practised with other similar materials, and in boiling alone, to say nothing of bleaching, the raw stock would lose at least as much as esparto, say 50 per cent; therefore, the cost of this prepared stock would be £19 per ton $\times 2 = £38$ per ton for a material very little, if any, better than esparto, the equivalent selling price of which would be say £8 per ton $\times 2 = £12$. I say nothing of the cost of the chemicals, fuel, labor, interest on plant, &c., &c., nor of freight to Europe, and general charges, all of which must, of course, be added to the above £38. The conclusion is obvious.

Kaing grass is a reed full of pith, and with many joints, which must be got rid of, as only the thin woody exterior shell contains the fibre; hence the low produce of 14 per cent. for the raw stock.

There are many other raw grasses in India superior to Kaing grass, but in my humble opinion no raw grass, or the stock produced therefrom, can come to compete with esparto.

The paper trade are much indebted to Mr. Buckle for the kindly interest he has taken in this question. India, and especially Burmah, abounds in indigenous raw fibres, many of which can be cultivated, and with Mr. Buckle's co-operation, I believe ere long we may hope to see some of the stock produced from such fibres introduced into the trade.

I may, perhaps, add that an essential point to be considered is that any fibre or fibrous stock introduced must be able to come into competition with esparto—that is to say, its cost no more, and its quality at least as good if not superior, when the old adage will hold its own, "Good wine needs no bush."

 LICENSE-TAX Report, 1882-83.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah in particular varies so much in the different provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

All correspondence must bear the full name and address of the writer, not necessarily for publication, but as a guarantee of good faith. We shall take no notice of anonymous letters.

WHAT WE KNOW, AND WHAT WE WANT TO KNOW, ABOUT CEARA RUBBER.

(To the Editor of the Ceylon Observer.)

SIR,—We know a good deal about experiments on a few individual trees, but we want to know something about results on a larger and more business-like scale. Mr. Gilliat is last in the field, and gives us interesting information, but, like his predecessors who have written on rubber, he relates results of a few trees only, and they do not add much to our previous knowledge.

We know that the trees will probably be short-lived. So say botanists, and its very rapid growth favour the idea. If, therefore, we are to make any profit out of it, we ought to begin at once to learn how that is to be done.

We know, that whether the tree be young or old, wounds made for the purpose of extracting its milk soon stop bleeding; and therefore a very little milk can be obtained from any wound, however it may have been made; nor can we obtain much milk at any one time, however many wounds we make. Trees subjected to the severest treatment, in order to ascertain the utmost yield of milk procurable, have proved, by their insufficient yield, that we must depend for any remunerative result on frequent tapping. We know, in fact, that we must be content to take a little at a time, and to take it often. What we want to know is how much we may take, and how often.

In the first place, therefore, we must devise a method of tapping, which may be often repeated without material injury to the tree or the bark. Every kind of incision that has hitherto been tried, whether vertical, horizontal, or arrow-shaped, has proved, sooner or later, to seriously injure the bark. It is true that the cuts or slits sometimes heal pretty quickly, but they are often a long time in closing, and produce serious scars. Some slits made several months ago on trees a year old are gaping yet. Although renewed bark has formed, it does not close over the wounds, which are now three times as wide as when they were first made, owing to the rapid growth of the trees. Perhaps, Mr. Gilliat's method may succeed better, but that remains to be seen. Meantime, it is satisfactory to know that a row of punctures will yield as much milk as a vertical slit or incision of the same length, whether such incision be made down to the cambium or be a mere shaving down to the lacteals. Punctures heal quickly, without material injury to tree or bark, and may be repeated at very short intervals. Trees have been thus tapped daily for several weeks without their showing any difference as compared with untapped trees in adjacent lines. Even when incisions heal completely, the renewed bark, especially in old trees, is very rough and intractable. For some time it yields very little milk, as compared with original bark, and is always rough and uneven. The methods of tapping by incisions seem, therefore, to be a needless as well as an injurious mutilation of the trees.

My first pricklers were intended to *tear* the bark a little, in order to produce a wound that would not close too quickly, but that is a mistake. A rough wound bleeds no longer than a smooth one; and a deep one, down to the cambium, yields no more milk than a shallower one that reaches the lacteals. (The pricklers are now being made with a guard to prevent the spurs going too deep, and are made to produce a *clean* wound instead of a rough.

The quantity of milk procurable from different trees of the same age, at the same day and hour, and from the same tree on different days, varies very much. This has been ascertained, but we ought to know the cause or causes of this variation, so as to adapt our proceeding accordingly. The factors of the variation are probably the hour of the day, the state of the weather, the condition of the tree, whether in flower, fruit, or flush, and the time of the year. The part which each of these factors plays remains to be ascertained, and can only be found by persevering and systematic experiment. Occasional or casual trials are of no avail whatever for this purpose. The milk drawn in the early morning is generally thin and watery, and becomes thicker as the day advances. After 10 o'clock, it sometimes becomes too viscid, but in the evening it again flows more freely. As a rule, milk may be drawn at all hours of the day, but it remains to be seen whether it would be better to discontinue the extraction during the heat of the day. The quantity of milk drawn, so far as it depends on the operator, is regulated, of course, by the length of the vertical row of punctures. Hitherto, a double row of 4 to 5 feet in length, on one side of a tree of about 5 inches in diameter, has been found to yield about 15 grains of dry rubber per tree. The daily collection of a cooly is about half a pound, and will probably be increased by improved appliances and with larger trees. We want to know

more about this, but, should it be found that trees will bear such extraction for 240 days in the year, the cultivation would be profitable, and there is reason to hope for such a result.

The curing of rubber seems to be a tedious business. My first collections were made in tins, and each day's collection formed a cake at the bottom of the tin. The milk coagulates so quickly that the cake, though soft, can be removed from the tin when the cooly returns from the field, but afterwards it dries and hardens slowly. Pressure causes a quantity of liquid to exude, and even when the cakes are hard they contain holes, like those in Parmesan cheese, full of liquid. Late experiments have been made with an apparatus which forms the rubber into strings, and these, when wound into a ball, look very pure and business-like, but even these balls, when cut in two, disclose some slight remains of liquid impurity. Probably Mr. Christy's suggestion of the use of a cheap spirit might assist in eliminating this muellaginous matter; but spirit is costly, and there does not seem to be much room for extra expenditure in the process. The cake rubber was valued at 2s. 6d. per lb., and the balls I think at 4s.

The foregoing is very imperfect, and shows rather what we want to know than what we have already learnt. Still, it is as far as I have got, and perhaps some of your correspondents can advance it a step or two further.

W.
[It must not be forgotten that most of the experiments yet made in Ceylon have been made on immature trees. As the trees grow older, it seems reasonable to expect if not more juice from a certain surface, yet a juice far less watery—almost pure gum, in fact.—ED., C. O.]

The Indian Agriculturist.

CALCUTTA, DECEMBER 1, 1883.

THE ASSAM AGRICULTURAL DEPARTMENT.

ON the 20th December last year, there appeared in the *Assam Gazette*, a notification to the effect that the Chief Commissioner of Assam offered a prize of Rs. 250 for the best essay on *Vasti* cultivation in the Assam Valley. The essay was to be written in plain grammatical English, and literary excellency was very properly considered of lesser moment, than a careful and orderly statement of ascertained facts. The object of the essay was to explain the uses which the ryot makes of his homestead land, and the value which he attaches to it, and the following points were set forth as those on which information was desired:—

1. The average area of the homestead, as compared with ryots' *rupit* and *faringhati* lands; how long it takes the ryot to bring his homestead into the normal condition; and whether the cultivated portion shows any marked difference in the nature or productiveness of the soil, due to more careful tilling and manuring, as is found to be the case in other parts of India.

2. The products of the homestead whether for food or other uses, as bamboos, plantains, castor plants, betel-nut, palms, mango, and jack trees, vegetables, tobacco, sugarcane, or sesamum (*oil*), &c.; the mode of cultivation of each separately the amount of labour and expense which it involves; the times at which the products are gathered, and the uses to which they are put; the mode of preparation for consumption, if the product is intended for that purpose; and the nature of the trade, if it is sold.

3. The return obtained by the ryot for the labour and money expended on his homestead; the extent to which it supplies him with articles of domestic utility, or petty trade, and generally contributes to the food and comfort of the family; what value the ryot sets upon his homestead, what price it commands, if sold, as compared with *rupit* and under permanent cultivation; whether the resignations of homestead land which annually occur are merely formal, are due to negligence in allowing portions of the homestead to be overgrown with jungle, or occur mainly in consequence of the ryot's removal to another village; and, if so, the reasons which are sufficient to induce the ryot to abandon his home.

The above list is not an exhaustive one, but merely intended to indicate what was required. All the information recorded on these, and other points connected with the subject, were to be of as precise and definite a character as possible. The Chief Commissioner reserved the option of withholding the whole or part of the prize offered, if none of the essays submitted should come up to a certain standard. The essays were to be submitted to the Director of Agriculture not later than the 1st of July 1883.

It appears that only one essay was submitted which was found unsuitable for reward, although it contained interesting information regarding the superstitions current among the peasantry in connection with the laying out and planting of a homestead.

The offer is repeated in the *Gazette* for November 10th, and the essay on best cultivation should be received in the Secretariat by 1st July 1884.

It is possible, the Chief Commissioner believes, that competitors may be deterred by the extent of the subject. He will, therefore, be prepared to accept essays on a part of the subject, as well as those professing to deal with the whole. Any competitor may submit a monograph upon cultivation and preparation of any one of the articles usually produced in the homestead area, viz., tobacco, plantains, castor-oil, betel-nut, palma, and bamboos, and the various kinds of vegetable commonly cultivated by the ryot. Such monographs will not be considered as entitled in any case to the whole reward, but will receive a prize corresponding to the importance of the subject, and the ability and thoroughness with which it has been treated.

As a model for the guidance of competitors the attention is directed to the memorandum on sugarcane by the Director of Agriculture which was published in the *Assam Gazette* of 22nd September 1883. It seems to us a matter of very considerable importance that the indigenous methods of cultivation should be known and diligently studied by all who wish to see modern methods grafted on the primitive indigenous agriculture of every province of India. We venture to think that not a few failures to influence native agriculturists in the direction of reforms and improvements on primitive implements of culture and traditional methods of cultivation, are due in a large measure to attempts at improvement being made before the conditions of labour, climate, race characteristics, and traditional methods of the peasantry have been thoroughly mastered. Agricultural implements are offered to Indian ryots which are in some cases beyond the limits of their means to purchase and work profitably, or which are unsuited to the physical and race peculiarities of the people who are expected to use them. It has, however, become quite apparent from the class of improved implements now offered to the ryot, that those points are receiving a greater share of attention than in previous years, and no doubt as a knowledge of the whole conditions of the ryot and his surroundings, his methods of working, his means, his farm lore, his superstitions, and all else that go to make him what he is, are better and more clearly known and appreciated, the better chance will there be of devising methods and implements which he will readily adopt. But after all, improvement is a thing of slow growth especially with races of people like the Indian peasantry, who are bound in the fetters of caste and ignorance, and wedded to the traditional usages of their forefathers.

In our estimation then, the Chief Commissioner of Assam has been wisely advised to obtain clear and reliable knowledge regarding the management of homesteads. On this as a foundation, there is good hope that improvement may gradually find a new basis. We are not however very sanguine that an essay quite after the heart's desire of the Chief Commissioner or the Director of Agriculture may be forthcoming in July of next year. The men who can write in English and who know the working of the Assam peasant's homestead, and the methods of culture of any of the ordinary crops, are, we should imagine, very few. The sons of well-to-do peasants who are being educated in English are, we should fancy, very few, and yet it is on this class that the best and surest hopes of improving indigenous agriculture are founded. Little, very

little, we fear, will be effected with the present generation of ryots anywhere in India. They will do as their fathers have done, and follow the methods and use the implements which have been followed and used for ages. If there is any hope for Indian agriculture it lies with the rising generation, and how these are to be reached would lead us beyond the scope of our present purpose. The Agricultural Department of Assam is wise in laying a good foundation of facts and realities before attempting to present the ryot with any new method, or any wonderful implement, which the lapse of years and the increase of knowledge would show even to their official imagination to be fearfully and wonderfully made.

AGRICULTURAL IMPLEMENTS FOR INDIA.

WITH the Calcutta Exhibition so closely approaching its opening, it is a matter of considerable interest to consider what way the Indian farmer can be benefited by implements and machinery, and we therefore welcome a contribution from Mr. Buck, of a list of those which have been reported to him as being suitable for introduction into this country. The list before us mentions 83 different implements and machines; but of these, 36 are ploughs of various descriptions, and the others miscellaneous machines, some of which it appears to us to be the height of folly to recommend to the ryot in his present condition. They may prove useful on large estates under European management; but where are the ryots who will purchase bullock gear costing £80 to 100 as prime-movers for driving cotton-gins costing £30 to 40; or sugar-mills at £70 to 100; or pumps at £50 to 60; or even winnowers at £20 to 30? We imagine that the office of the Agricultural Department is specially to aid the ryot, and not the European planter or merchant, for the latter can well take care of himself, whilst the former is a veritable child in such matters, and needs leading with a careful hand. Not that we object to Mr. Buck assisting the planter by letting the man of Bengal know what his brother in Madras is doing, but we believe that the planter may be left to take care of himself in such matters, and that he does not in any way represent the agriculture of India, but only a small special branch thereof. Mr. Buck is of course not responsible for the opinions he quotes in the list he publishes; but the inclusion therein of machines such as we have noted, in a manner gives the imprimatur of the highest agricultural officer in the country to recommending them for use in India. This is, no doubt, in a measure due to the fact that Mr. Buck has no special knowledge of agriculture himself, and as far as we know, has no one near him who could assist him in such matters; and as long as the Government of India persists in making its Director-General of Agriculture a mere departmental secretary to indite "notes" on matters agricultural, and at the same time requires him to administer the revenue system of a vast empire, so long will such absurdities accrue. Mr. Buck, it may be said, has only compiled the opinions of local officers; but they are as unfitted, as he doubtless allows himself to be, from their previous training to see what can be done in this matter. No doubt one of the greatest errors in the introduction of implements into India, has been the attempt to induce the ryot to accept articles which have been designed for a totally different set of conditions. The ryot does not care much for labour-saving machines, as his labour is to a large extent unpaid, consisting of the work of himself and his family, whereas in Europe and America labor is scarce and highly paid, and there are a great many other openings for it besides agriculture. It appears to us that for most ryots, the implements that can be recommended may be counted on the fingers of one hand. Besides a good plough, a winnower, and in some cases a maize-sheller or a sugar-mill, there is as yet but little opening, except in the improvement of the cultivator's minor tools, which are generally very rude and inefficient. There is, however, a considerable opening for the introduction into some parts of the country of old established native implements used elsewhere, but unknown there. The Exhibition should teach our agricultural authorities this. We believe that extensive collections have been made from all the provinces, and we hope that advantage will be taken of the

opportunity, to assemble all the chief agricultural authorities of the different Governments, so that a full discussion may be promoted of the subject, and that they may learn from personal contact what they are each doing. Such a Conference could not fail to be of great value; and as we learn that some sort of conference of the Directors of Agriculture in the different provinces is to be held shortly, we hope they will bring their technical advisers with them, and so turn the great 'show' to the best account to the country. There is no doubt a good deal of ignorance existing in the departments of the various provinces of India regarding what has already been done in others. This could easily be avoided, if the office of the Supreme Government did more to call the attention of the authorities in each province to the results obtained elsewhere, and so fulfil its proper function. So long, however, as it is the practice to make use of local and vernacular terms to such an extent as we see in the list before us, which is a step in the right direction, so long will the authorities remain ignorant of what is being done outside their own particular sphere. In North India, the practice is perhaps most common, but there would seldom be much difficulty in a practical agriculturist finding a proper English equivalent for all the implements in use, and it would surely be far better if the use of the maund, which varies in different provinces as the unit of weight, were abandoned, and results stated in pounds, so as to be clear to every one. The Madrassee does not know what the "kharpi" or "charpai" means, nor does the Bengali understand what a "guntaka" or "papetam" is. For a list such as Mr. Buck's, to be of general value throughout India, such words should be avoided, and their English equivalents given, as English is the only language which can be said to be at all universally understood in India. We should be very glad to know what is the peculiarity of a "beam" plough, as reported on by the N.-W.P. Department of Agriculture. All ploughs have a beam; but we imagine that what is meant is that a fixed pole or shaft, after the style of the native plough, replaces the ordinary horizontal beam in such ploughs. The point, however, should be cleared up. Absurd mistakes there are also in the list, as for instance, talking of the "loaded wheels" of a grubber. Are there some new ideas concealed under this expression, with which we are not acquainted, or is it simply that the writer did not know what he was talking about?

A good plough is of course the first requisite of the farmer in all countries, but the manner of it will differ according to the conditions met with. Thus we find a different general pattern adopted in America to that preferred in England, and it is scarcely to be expected that in a country so peculiarly circumstanced as India, the implement adopted in either of these countries should be suitable. As yet we do not believe that the plough for India has been designed, nor do we think that any one pattern will be universally adopted. We know that this is the opinion of practical men, although we find so good an authority as Mr. Benson in a recent report, remarking that "for the greater part of India one general form of plough would suffice." It seems to us that he has been misled into inferring from the present general similarity of the native plough throughout India, that a like similarity in an improved plough would be equally acceptable, forgetting that the acceptance of an improved plough would denote progress, and that with progress must come divergence in form, to meet the special wants of the farmer of different soils. Do we not see in England, where the general principles to be adopted in the plough have been established for 70 or 80 years, that the varieties are almost innumerable? Under these circumstances, it is not surprising that the opinions on Mr. Buck's protégé, the Kaiser plough, should be so divergent, nevertheless we believe that the opinion of the majority of reporting officers against it, is in the main correct, for the implement is far too flimsy and weak of construction for ordinary farm use. This is natural when the price—Rs. 6—is considered; for what sort of an implement can be expected for so little money, and particularly when the materials have to a large extent to be imported? Many persons have been led altogether astray in their endeavours to devise a plough suitable to the ryot, by trying too closely to approximate their designs to the native one, both in cost and manner, sacrificing thereby a large degree

of efficiency and durability, and turning out a low-priced, but extremely expensive article. A good plough must be, of all things, capable of standing hard usage, and must invert the soil thoroughly. These things cannot be done by a plough turned out for Rs. 6. It is, however, possible that, by adding a few rupees' worth of material and labour, a far better and more serviceable implement may be constructed. We believe that Rs. 12 would probably be the lowest figure that should be aimed at. It is a figure well within the means of a very large proportion of our ryots, and one which would admit of good work and material being put into the plough. To go lower is to sacrifice durability; and is it likely that the ryots will fully appreciate a plough which needs to be replaced every year or two, just as their present one does? It is true that it is far more economical for the farmer, to invest at once in a thoroughly well constructed plough at a cost of Rs. 20 or 30, but at present it would be far more difficult to persuade the ryot to invest that sum than half the amount, and to a certain extent it may be wise to pander to his weakness, though in his true interests the higher-priced plough should be pressed upon him, and perhaps a plough might be obtained for less than Rs. 20 even, if the Government of India would hunt the world over for them, and their makers. For we observe in Mr. Buck's list, a plough of Swedish make reported on by Mr. Robertson as "the best and cheapest plough yet introduced into India," and costing in Madras Rs. 16 at, we believe, wholesale rates, so that our dealers should be able to sell them for Rs. 18, and make a fair profit. While on this point we may note that in our advertisement pages, and published recently in the Madras papers, we have seen a plough advertised for Rs. 15 and Rs. 15-4, which we notice Mr. Robertson quoted at Rs. 10 in Madras; and we would venture to point out to importers that if they wish to push the sale of such ploughs by the thousand, they must accept a lower rate of profit than is customary in the implement trade in England, as they should remember that their true interests lie in the sale of numbers, and not in getting a large price for a few.

One consideration which the remarks in Mr. Buck's list brings up, is that of tail-twisting and the necessity for it. The first question is—Is the practice general or universal? The second—Is it necessary? To both of these we answer decidedly, "No!" The practice is chiefly adopted in carts and not in ordinary field work, where the goad is used, and in a very cruel manner, too. Mr. Sineaton in Burmah says that in his province there is no such practice. It is true that the ryot likes to be near his cattle; but is it not possible that this is almost entirely due to custom? If so, is it worth while sacrificing the efficiency and convenience of a plough to the custom? We do not think it is, to the extent that many are disposed to do, in adhering as closely as possible to the upright handle of the native plough. To the ryot, the upright handle is, we acknowledge, very taking, but unless he really grasps the idea that the benefit to be derived from a plough does not arise in its handle, but in its share and mould-board, what good arises from his appreciation? With an upright handle, the ploughman loses control over his plough, and is therefore unable to do good work unless the soil is very even in texture and soft. Another point which is often aimed at, is to replace the usual horizontal beam of a plough by a fixed inclined pole or shaft, as in the native plough; and it is questionable whether this is a step in the right direction. One thing is pretty certain, and that is, that by doing so a native prejudice is met; but in doing so, efficiency is lost. The cattle are placed in a very inferior position for the exertion of their strength, and have to put forth more force to do the same amount of work, than would be needed with a plough so constructed that the line of draught were more correctly disposed. There must be, in the case of the fixed-pole plough, a great downward pressure on the fore-quarters of the cattle which they have to support in addition to performing the work of ploughing pure and simple, i.e., inverting the furrow-slice. For an animal to exert its full strength in drawing anything, it is necessary that a line drawn from the centre of resistance to the point of attachment should fall very slightly below the centre of gravity of the animal, and be as nearly as possible in

the horizontal. In the plough, the centre of resistance lies an inch or two behind the share on the mould-board, about two inches above the level of the soil. It seems to us, then, that it is a grave mistake to shorten the plough too much, and to be very doubtful whether the advantages of a slanting pole are sufficient to compensate for the undoubted strain which such an arrangement puts on the cattle. We have also the experience of various experienced agriculturists and of Mr. Smeaton in Burma, that the long-stilted European ploughs can be managed by native ploughmen with skill, when doing a good day's work. These considerations must be borne in mind by any one trying to make a really good plough; and we venture to hope that the Government of India will take this plough question up seriously, and endeavour, with the agricultural, engineering, and general knowledge at their disposal, to work out some really durable form or forms which can be placed before the ryot as the best for him at the present time, and at a price he can be persuaded to give. When this is done, English manufacturers and local makers will compete to obtain the hold of the vast market that India must become in the future. There are signs that a demand will very shortly spring up, and it will arise the sooner if the steps we suggest are taken. Beside the vital importance of the plough for India, all consideration of other machines sinks into insignificance, and we do not propose therefore to touch any other item of Mr. Buck's list.

AGRICULTURAL IMPLEMENTS AND MACHINES FOR INDIA.

A GOOD deal of attention has of late been attracted in this Presidency to the movement which has set in, particularly in the Bellary district, towards the adoption of European ploughs by the ryots, and we welcome therefore a list, which has recently been published by Mr. Buck, of agricultural implements which have been found useful in India. Though we cannot think it exhaustive or, perhaps, quite fairly compiled, it cannot fail to be useful to those who are interested in the improvement of husbandry in this country. Every one who has studied the question at all, has long ago admitted that the first and chief want of the ryot in this respect is a better and more efficient plough; for the native implement has over and over again been shown to be a very expensive and inefficient article for the performance of the work desired of it. It is, no doubt, procurable at a very low price, but it must be evident that the cheapness of any implement does not lie in its prime cost, but in the cost of doing work with it. The objects of a plough are, first, to stir and loosen the soil, and, secondly, to invert it, and thus expose it to the ameliorating action of the air; and in every country where agriculture has made much progress, the latter is regarded as being as, if not more important than, the former object. The native plough is almost incapable of inverting the soil, and in simply stirring it is very far from being economical. We are not surprised, therefore, that the greater portion of the list before us is filled up with ploughs of various sorts. It is, however, a great pity that a little more trouble and expense have not been directed to its preparation, for there is no possible means of any one finding out from the list itself, what sort of a plough it is that is being referred to; a few illustrations of these ploughs and other implements which have been found most suitable for use in different localities, or for special purposes, would have increased the value of the list tenfold.

Turning now to the implements themselves, we notice that the "Kaiser" plough, brought out by the department of which Mr. Buck was not long ago the head, is placed first; but it is curious that, though so prominently indicated as being the plough for India, out of seven opinions quoted regarding it, only three are favorable, and one of these is from the department which issues the plough, and the other two are considerably qualified; while the remaining evidence given is adverse. Strangely enough, no opinion from Madras is quoted at all, although we find that in the year 1869, the plough was tried at Saidapet, and reported on as follows:—"The plough is roughly finished, is without a wheel, and is unfitted to undergo the treatment ploughs usually receive in the field, while it does not turn over the furrow slice efficiently from the bad form of the mould-board." This opinion agrees with that of the Superintendent of the Kandesh farm who says that the plough is "much too light and flimsy for any soil on this side,"

and an opinion from the Central Provinces. In the opinions on this plough, a remark comes from Burma to the effect that there is no necessity that the ploughman should be near enough to his cattle to be able to twist their tails. A good deal of nonsense has been, and still is, frequently written on this subject of tail-twisting, but a good deal of experience and close observation in this part of India satisfies us that it is utterly unnecessary, and that in many localities is not practised on plough-cattle at all, whilst we have all seen at the ploughing matches held annually at Saidapet, the ploughmen of the farm driving their cattle with a whip and rope-reins. In pursuing the idea that it is necessary to the ploughman to be very near his cattle, a great deal of efficiency in and convenience of control over ploughs, has been sacrificed in India. We have shown that the "Kaiser" plough is not the unqualified success that its designers would have the world believe it to be, and it is not surprising, for they have gone to work on what we believe to be an altogether wrong principle in trying to turn out a very low priced implement. The first cost of these ploughs is Rs. 8, and no rational being can expect a really useful article that will stand the wear and tear of farming operations for that sum. Undoubtedly ploughs for India must be in the present day lower priced articles than those used at home; but it is a mistake to rush to the other extreme, and to try and turn out an implement at a price as nearly as possible the same as that of a country plough, or the result must be, as we see in this plough, a light and flimsy article which will not stand hard work, and is not thoroughly efficient. Although, perhaps, there are many thousands of ryots who cannot afford Rs. 10 for a plough, there are as many or more thousands who can well afford Rs. 10 or 20 for a thoroughly efficient and durable one; and it is the latter class whom it is most desirable to help and encourage, for the former are only a drag on the country, and the sooner they take their proper position as farm laborers the better. Of course, there will always be men who would rather have low-priced implements, and for these they may be made, but it is a mistake to encourage the purchase of such implements as Mr. Buck would appear to wish. In a list of the implements that have been found useful in India, we are surprised to notice the omission of what Mr. Robertson in his report for 1881 calls an "improved country plough," and which appears to have met with considerable favor in Tanjore and elsewhere, and also the omission of Messrs. Massey's ploughs, which we noticed at the time of the late Agricultural Exhibition. Perhaps it is that Mr. Robertson did not supply the necessary information regarding the implements to Mr. Buck in some of his reports. The fact of the omission, however, remains, and lessens the value of the list.

We have devoted so much time to the discussion of the general subject of ploughs for India that we must pass rapidly over the other ploughs enumerated in the list. The most prominent, besides the "Kaiser," among those indicated as having found favor are several patterns of Swedish manufacture, which have been selected after numerous trials of various ploughs as being, in the words of Mr. Robertson, "the best and cheapest ploughs yet introduced into India." A large number of them were imported last year by Government for illustrative distribution in the Presidency; the price of these ploughs is Rs. 8, and they are very strongly constructed, but it is to be feared that they are too heavy for general use in a good many of our districts, where only small cattle are obtainable. These ploughs are made by the Öfverums Bruk Manufacturing Company in Sweden, and contrast most favorably as regards price and material with those made in England. They were first brought to notice in the report on the Madras representative at the Vienna Exhibition, on the strength of which a number of different sorts were got out from Sweden, and underwent trial at Saidapet. These trials resulted in the selection of the plough referred to. Some of the larger patterns obtained at the same time, which were found unsuitable for general use, have after trials made in the Bellary District in ploughing up the black cotton soils, been adopted there in preference to the clumsy and inefficient large native plough (*pedda maddaya*), and have been imported by Mr. Sabapathy Modelliar in considerable numbers for sale to the ryots, at prices ranging, we believe, from Rs. 50 to 60. Seeing how satisfactory were the results of the observations of an amateur, Colonel Michael, at Vienna, we hope that the Government of India have taken steps to secure the best qualified opinions on the agricultural implements that may be exhibited at Calcutta. Advantage should be taken of the opportunity afforded by the probable presence of the representatives of the great manufacturing firms of Europe and Australia to assemble a committee there, consisting of persons of wide general experience of the ryots, and special agricultural and engineering knowledge, to endeavour to design

a plough suitable for general introduction into the different parts of India. For it is our belief that the plough for India has not yet been devised, and that it is worth the expenditure of a great deal of time and money by Government in trying to put before the ryots a really cheap and efficient plough. Better ploughs will lead to better and more certain crops, and enable the ryot to devote a larger portion of his holding to industrial and fodder crops, thus increasing the supplies for export, and benefitting the live-stock of the country.

There is a good deal of amusement to be obtained by the initiated from Mr. Buck's list, in the ludicrous jumbling together of implements of totally different characters, and in the remarks on these implements. Thus we find the name "Farnwrist" for "Turn-wrest" given to a plough; and the "broad wheels" of a grubber by Messrs. Coleman and "Mortar" for the "broadahares" of an implement by Coleman and Morton. No such mistakes as these would be made by any practical agriculturist, nor would one mix up chaff-cutters and winnowers together, or put corn-crushers and sugar mills in the same category.

Next to the plough, perhaps, the most useful European implement to the ryot is the winnower; for though during the season when most of the threshing is now done, there is seldom much chance of rain, it is a great pity that the ryot is driven by the absolute necessity of having fine dry weather to thresh and winnow his corn as soon as he harvests it. With a good winnower, he is independent of the wind, and of the weather also to a great extent, and can thresh his corn at the time he finds the market most favorable to him; whilst in the case of large farmers the machine, if a good one, will save expenditure, and do the work more efficiently than can be accomplished by the wind. But though the winnower is very valuable in India, and is reported on favorably by most of the officers mentioned in the list under consideration, the only evidence given regarding threshing machines is adverse, and this we find agrees with the experience noted in Mr. Benson's Saidapet Farm Manual. Machines for shelling maize from the cob have naturally been carried to the greatest perfection in America, but we were surprised to see in a table given by the Director of Agriculture for the N.-W. Provinces regarding a machine costing Rs. 78, which he recommends for its great simplicity and efficiency, that it was capable of only shelling 780lb. of grain per diem; for on turning to the Saidapet Farm Reports for 1879, we found a record of an experiment in which the "Eagle" maize-sheller, costing Rs. 40, turned out 7,582lbs. of grain in a day, and it is remarked that the figures were not favorable. The respective amounts of grain which would be shelled for one anna at these rates would be, as far as we can make out amongst a confusion of maunds by the one used in the N.-W. Provinces, 107lbs., and by the "Eagle" 1,516lbs. The fact that in two parts of India two departments exist for the same general purpose, and one does not know what has been already found out by the other years before, does not say much for the interest of the officer of the N.-W. Provinces department in their duty. Several chaff-cutters are very favourably reported on, and in time should come into use, for they undoubtedly are most valuable in economising fodder, by enabling cattle to eat and digest much more of the straw than they can when it is in its natural state. In water-lifts, there is still, we believe, a good deal to be done, for all those which have heretofore been devised have considerable drawbacks; thus, the one recommended by Mr. Robertson, although very useful for lifts of from 15 to 25 feet, is inefficient above the latter height, and is also costly to erect. It is to be hoped that some of the mechanical ingenuity which has developed simple and efficient machines for other purposes in England and America, may be directed to this subject. One thing the list confirms, by the evidence given in it, is an opinion we have before expressed that windmills, though at times they might be useful for water-lifts, can never from their uncertain action be well suited for general adoption, or where water is required regularly at certain seasons. Messrs. Thomson and Mylne's Beheer Sugar-mills appear to be meeting with a great sale in Northern India, and the reports regarding them are almost universally favorable. We learn that a sale for them is springing up in the Bellary district, from the action taken by our local Agricultural Department.

In conclusion, we may remark that Mr. Buck's list would have been far more valuable if it had contained remarks on and descriptions of the native implements which are found to be useful and efficient in different localities, for it is a peculiar thing that the use of implements is often very local, as, for instance, in this Presidency, the use of the bamboo seed-drill is almost entirely confined to the Canarese and Telugu districts, and does not extend over the whole of these districts. The collection of native

implements sent to the Calcutta Exhibition should illustrate this, but there ought to be in Madras a similar collection for the benefit of the people of the Presidency, and to guide our local lights in the way they should endeavour to assist the people, of one part in bringing the good things of another, to notice. We have been trying too much to introduce from abroad things devised for an altogether different set of conditions, and do not fully acquaint ourselves first with what the country itself contains of value. The sooner Mr. Wilson and his department set to work, and make themselves acquainted with the "agricultural machines and implements which have been found useful and efficient in India" by the ryots themselves, the sooner will real progress in this direction set in.

EDITORIAL NOTES.

SYRIAN SILK.—The *Central-Blatt für Textil-Industrie* gives some details as to a vegetable substance somewhat resembling silk, to which attention has lately been drawn by its having been exhibited in Greece. It is stated that this substance is a silky-haired portion of a tree-like shrub which comes originally from America, but is found in Syria and the South of Europe (*Asclepias Syria*), of the family of the Asclepiads. It is also known as the Syrian silk-plant. The substance in question is used for stuffing very soft cushions, when mixed with silk and wool. This Syrian silk is used in different tissues. The milky juice of the plant is said to be poisonous, and the tough stalks can be used in the same manner as the corresponding portions of the hemp-plant.

It appears from a report recently issued by her Majesty's Secretary of Legation at Buda-Pesth, that the progress of the iron manufacture in Hungary has been greatly retarded by the want of suitable fuel, and, at the present time, though inferior kinds of fuel are used with advantage, yet the absence of a better description is still a great drawback to the production of iron in this country. Vegetable fuel is of necessity used by the largest iron works of the country, and of forty-eight works with fifty-six blast furnaces, only four used either coke or coal, the remainder using charcoal. Ironstone deposits are, as regards their quality, variety and extent, at least not behind those of the neighbouring countries. Spathic iron is found in several districts, and especially in Gomor, Szepes, Abany, Toma, Zolom, Liptai, and Szoreny. The "ore mountain" of Dobschau, with its numerous deposits, running, in some places, to a thickness of thirty-six yards, yields ores mainly worked in the open, which contain from 2 to 4 cent of spathic iron of great purity and value. Of late years much importance has been attached to the spathic and brown ore deposits of the Zipser districts, especially in the vicinity of Vorospatak, owing to the export trade with Upper Silesia. Of still greater importance are the mines in the Hunyad district, containing extensive deposits of brown ore merging into red. These deposits extend, with partial interruptions, over an area of more than nineteen miles. The future of the Hungarian iron manufacture depends on the production of superior iron, as the cost of production is materially increased by the daily growing necessity of bringing the iron from greater distances. A very large annual export of iron ore now takes place from Upper Hungary, the amount averaging over 125,000 tons. Notwithstanding that the forests in the immediate vicinity of the ironworks are much reduced, and in some cases entirely exhausted, yet there is still an abundance of wood and charcoal in Hungary. It is estimated that the extent of forest land considerably exceeds 6,175,000 acres. The annual growth of timber in the forests is 14,000,000 cubic feet, which could produce—if only a third of this amount were used—over 500,000 tons of charcoal pig iron annually. The forest lands are, however, in almost impenetrable mountain districts, and at a great distance from every means of transport, thus making them practically unavailable for manufacturing purposes. The management of the ironworks is now almost entirely in the hands of technically educated and practically skilled men, and the results are very

satisfactory; for example, the works of the Salgo-Tarjan-Rima-Murany Company produce 800lbs. of pig-iron with not more than eleven bushels of beech charcoal. The Royal Works of Goresda Hunyad use rather more than twelve bushels of charcoal for every 800lbs. of pig-iron, and the other works use about the same proportion. The production of these smelting works varies per blast furnace from 300 tons to 520 tons per month, according to dimensions of furnace and description of iron made. At the present time Hungary possesses an aggregate of forty-one pig-iron works, and fifty-two blast furnaces in operation. The yearly production of the whole country amounts to 167,500 tons, of which 17,000 tons take the form of castings.

In the current number of the Linnean Society's journal, amongst some "Notes on New Economic Plants received at Kew," by Mr. Thistleton Dyer, we find the following:—"Various species of *Myrica* yield a wax in different parts of the world. The berries are simply boiled, and the wax rising to the surface is skimmed off and moulded into cakes. Mixed with tallow, the wax of *Myrica Cordifolia*, L., is used at the Cape in candle-making. *M. Corifera*, L., yields a similar product in N. America, and a variety of species are utilised in a similar way in Central America. The Kew Museum possesses a candle of *Myrica* wax from the 'W. Indies,' presented by Professor Ansted, and a moulded block of what is probably a similar material from St. Domingo. For the first authentic sample from these islands we are, however, indebted to D. Morris, Esq., F.L.S., Director of the Public Gardens and Plantations, Jamaica. The following particulars respecting it were contained in a letter, dated March 15, 1883:—"I am sending in a separate parcel a small specimen of wax prepared by Mr. Hart from one of our native trees, which may be of sufficient interest to have a place in your Museum. It has been prepared from the seeds of *Myrica microcarpa*, Benth., an amentaceous plant, growing abundantly on the hills of Jamaica at elevations of about 5,000 feet. The seeds were simply boiled with water for about half-an-hour, and then allowed to cool, the wax forming (when cool) a cake on the surface of the water. This was melted again in an earthen vessel to allow the dross to settle to the bottom, after which the wax becomes clean and clear." As the tree is very abundant in Jamaica, and is of no use except for firewood, it would be a very desirable thing if any commercial use could be found for the wax, as it can be prepared in such an exceedingly simple manner."

PROFESSOR BREWER, Special Census Agent appointed by the American Government, has issued his report upon cereals, which embraces many interesting facts. It appears that for the census year of 1880 the total production of the six principal cereal grains in the United States amounted, in round numbers, to 2,698,000,000 bushels, an average of 53.8 bushels per head of the population, and an increase of upwards of 94 per cent since 1870. It is an important fact in connection with this enormous increase that it was not chiefly due to the cultivation of new lands in the west and north-west, but is more largely due to grain in farming regions already occupied in 1870. The chief advance was in regions which have been some time in cultivation, and in lands ranging in value from 30 dollars per acre and upwards. The grain consumption *per capita* in the United States is a fraction over 40 bushels, but in Europe it is less than 18 bushels. It is 13 bushels only in Austria, 30 in Denmark, 24 in France, 23 in Germany, 30 in Great Britain, 16 in Holland, 9 in Italy, 17 in Russia, and 17 in Spain. The crop of five contiguous States—Ohio, Indiana, Illinois, Missouri, and Iowa—amounted to over 50 per cent of the entire American grain production. Most of the grain of the United States is grown in regions where mixed farming is practised, and on farms of moderate size. Professor Brewer explains that by mixed farming, he means the growing of green and grain crops and the production of animals on the same farm. The topographical tables of distribution show that the prairie region produces over 27 per cent, or about three-eighths of the whole. The central region, which comes next, produces nearly as much as all the other 19 topographical divisions into which the country is dissected for this investigation. In every instance the grain has its largest production at

an elevation of between 500 and 1,000 ft. above the level of the sea, where more than 52 per cent of the whole product is grown. Upwards of 90 per cent of the grain of the country is grown between the elevation of 100 and 1,500 ft. Bread grains are grown chiefly in the belt, where, owing to winter's cold, comforts are secured only by labour. A little less than 70 per cent of the whole grain productions is in regions where the mean temperature of January is below 30 deg., and nearly three-fourths where the average for that month is below the freezing point. More than 40 per cent is produced where the annual temperature is between 45 deg. and 50 deg.; 74 per cent where it is between 45 deg. and 55 deg.; 84 per cent where it is between 45 deg. and 60 deg.; and over 91 per cent where it is between 40 deg. and 60 deg. Thirty per cent is grown where the annual rainfall is between 40 in. and 45 in.; 60 per cent where it is between 35 in. and 45 in.; 85 per cent where it is between 30 in. and 50 in.; and 94 per cent where it is between 25 in. and 55 in. Forty-seven per cent is grown where the mean July temperature is between 75 deg. and 80 deg.; and 86 per cent where it is between 70 deg. and 80 deg. With the exception of Pennsylvania, in all the large grain-growing States more than four-fifths of the farms are farmed by their owners. Professor Brewer calculates that not less than 80, and probably more than 85, per cent of the total grain produced in the United States is grown upon farms which are occupied and managed by their owners; and the greater portion of the grain is grown on farms of over 100 acres. How long this proportion of cultivation by owners will last is another question.

THE *Moniteur des Filés et Tissus* calls attention to a description of vegetable wool called *Kapoc*. It comes from Java, and a specimen is on view at the Amsterdam Exhibition. It arrived at Amsterdam in its leathery covering, being itself enveloped in the seeds. It is then freed from both, and is carded so as to make a very light mattress wool, worth about 8½d. per pound. One of the houses engaged in this operation had made trials in spinning and dyeing this material, but the filaments are said to be like strings, and their industrial application is consequently a matter of uncertainty.

THE *Tobacco Leaf*, published in the tobacco interest, estimates the loss on the tobacco crop of the country by hail, and later by the frosts, from the 6th to the 10th of the present month, at fully fifty thousand cases of the seed leaf crop of this year. Its telegraphic reports from the various tobacco-growing districts show the frost damage through the entire New England states, New York, Pennsylvania, Ohio, and Wisconsin, though Pennsylvania suffered the least of any of the states named. It claims that at the best not more than three-fourths of the crop planted will be harvested, which will favorably affect stocks now in the hands of dealers, and enhance the value of such of the crop as has been saved in good condition, and thinks holders of seed leaf will be justified in assuming a firm attitude in relation to prices.

CALIFORNIA raisins are made from the Malaga grapes, and are large and of excellent quality, and are acknowledged to be superior to the foreign. They are also fresher, as they never have the ethery taste given to the foreign raisins by the sea-voyage. The grapes can be grown so cheaply in California, and the raisin product is increasing so rapidly that in a few years, possibly in 1885, it is confidently expected that the California raisins can be laid down in this market at \$1.25 to \$1.30 for a 24lb. box, at which price the foreign raisins cannot compete with them. At present the freight on the California raisins is 1½ cents per pound, which amounts to 25 cents on 30 pounds, and it is probable that as the shipments East increase, the freight will be lowered a little. The foreign raisins pay a duty of 2 cents per pound and ½ cent per pound freight, and this on a 30lb. box would amount to 50 cents, and this 50 cents for freight and duty must be subtracted from whatever the Spanish raisins sell at against 25 cents to be subtracted from what 30lb. of California raisins sell at. It is claimed by the Californians that they can produce raisins fully as cheap as the Spaniards, and that in a few years they will

control the American market. In addition to their superior quality, buyers will be attracted to California raisins for another reason. They are honestly packed, the bottom layer being fully equal to the top, and the boxes have always full weight.—*Boston Commercial*.

THE *Breeder and Sportsman* says:—"We do not suppose that one in a hundred can tell why he eats salt himself or gives it to his stock. It is important that our food and the food of our stock shall be made palatable, for there is no question at all that the animal system will do much better upon a food that is relished than upon a food that is not. . . . Another, and more important reason is, that salt is found in every portion of the system, giving us to understand that nature intends it as the vital part of the animal structure, and that it must, therefore, be supplied in one way or another. As a usual thing, the mineral elements of the animal system are abundantly supplied through the food, without any especial effort to that end. But it is not so with salt. The food of animals does not naturally contain a sufficient supply of this element. It therefore must be added, and unless it is, the animals fall off in condition. The structure is wanting in an important element of strength: just as a wall would be wanting in strength if there were no lime in the mortar, and just as the animal structure would be wanting in strength if there was an insufficient supply of salt. Careful experiment has demonstrated this. It is shown that salt is a necessary element of complete animal structure, and that without it the animal will become sleepy and weak, especially in the extremities, finally dying for want of this mineral element. Prof. Foster, of the University of Munich, conducted a series of experiments upon pigeons and dogs, to see what effect a diet as devoid of mineral as possible would have. The pigeons were fed with starch and casein, which were as free from ash as possible, and the dogs with meat from which all mineral matter was extracted. The result was always the same—the muscles growing rapidly weak, especially at the extremities, and finally, cramps and shivering showed great irritability of the nervous system. . . . Indirectly, salt doubtless is an aid to digestion, for it certainly has a tendency to keep the alimentary canal from clogging, and, that free, the entire machinery of the system is freer to perform its offices.

Salt is a natural absorber of moisture, and in the performance of this office it keeps the contents of the canal from becoming too dry and packed. It also operates in a similar way upon the food while in the stomach, and thus, by enabling the solid food to secrete and retain a due amount of moisture, help the digestive organs in performing their work. No animal can remain in a condition of health and vitality without a sufficient quantity of a combination of foods containing all the elements or constituencies to properly nourish the animal. The bone, muscle and tissue must be fed in proportion, and the fuel furnished in the carbon, which supplies the heat. The vital forces abound in the nitrogenous or glutinous and phosphatic elements, which should be supplied liberally to all animals, properties which are found in corn in a very small degree. Salt, as we stated before, encourages the absorption of a large quantity of water, so that the food is conveyed in such a consistency of liquidity that it is easily and readily absorbed as nourishment. The food of all animals requires a certain degree of bulkiness, in proportion to its qualities of nutrition, and the salt aids in this expansiveness, as indicated above. As exercise or labor develops the muscles, so the grasp of the digestive organs upon a sufficient quantity of available food invigorates and increases their power of utility. Wheat, bran, oats, and the coarse kind of provender combine the properties of nutrition suited to the best results of growth and development and bulkiness of food. Then, again, salt is unquestionably useful as a means of destroying the numerous parasites which are found in the animal system. The army of animal-cule which is constantly preying upon the muscles and tissues of the body would soon devour it, if they were not expelled or killed, and parasites which increase so rapidly and work so incessantly that they sap the foundations of life. As a rule, however, nature enables the system, with proper care, to hold

its own against them, and salt is undoubtedly destructive to the life of these destroyers.

PROFESSOR THOROLD ROGERS writes as follows:—"A good many persons have been making experiments on ensilage during the past year. But nearly all have tried it with a view to seeing whether green forage would keep sound in an airtight and watertight pit, duly weighted on the surface, in default of being absolutely closed. That it would keep under such conditions ought to have gone without asking.

"What ensilage does is to (1) increase the nutritive powers of green forage; (2) to obviate waste; (3) to save time; (4) to increase the productive powers of the soil. It does the first, if in no other way, by making the forage more digestible; the second, by saving a deterioration by exposure to weather; the third, by putting the least possible time between cutting and storing; the fourth, as a sequence of the third, by enabling the farmer to cut a double crop yearly, by giving him opportunity for enlarging his stock of cattle, and by enormously increasing the amount and value of manure.

"I know from the correspondence which I have had (at one time nearly that of a department in a Government office), that the construction of silos is going on on the new plan practised in the United States, and sketched in my little book on the subject, in India and Australia as well as generally in Europe. A day or two ago I gave leave to a correspondent to translate my book on ensilage into Swedish.

"Most English silos of which I have read are made in too shallow masonry. It stands to reason that this increases the expense per cubic yard. They should be from 20 to 25 feet deep, if they are to be made in the cheapest way. I believe that my friend, Mr. Samuel Whitbread, has made the best hitherto constructed in England.

"The main object of ensilage is to get two crops a-year off the same land. Silos are profitable if they obviate loss; most gainful when they increase produce. I should add, however, that cattle need cleanliness and ventilation as much as human beings do, and I do not wonder at disease being prevalent in English herds, and for the matter of that in flocks, when I see the dark, filthy dens in which they are generally housed, and the wasteful way in which they are exposed to weather. Our forefathers kept their sheep under cover from November to April.

"Had silos been common in England, millions of pounds worth of fodder would have been saved last summer, and not much less worth of aftermath would be saved now. I should have thought that this was the time in which English agriculture could not afford to neglect small economies, let alone great ones."

PROFESSOR WILEY, the successor of Dr. Collier as Chemist of the Department of Agriculture at Washington, in a recent letter to the *Rural World*, of St. Louis, says: "At Paris it was found that the invert sugar was always present in sorghum juices in greater quantities than sucrose. In Italy the sucrose was found to be more than ten times as much as the non-crystallizable sugar." May not this be one of the Professor's "little jokes," like that you mentioned a short time since about the "glucose honey," which rather irritated than amused our bee-keepers? I see by the report of the National Academy of Sciences on sorghum sugar, page 62, that in 1854 Vilmonin found in the juice of sorghum grown in the suburbs of Paris (Verrieres) 11.75 per cent of sucrose and only 4.25 per cent of glucose; and I also now have before me the report of the director of the experiment station at Avignon, in France, who says that the sorghum juice grown by him gave 16.3 per cent of crystallized sugar and 1.7 per cent only of glucose; and he adds that his results are "fully in accord with those obtained by Peter Collier at Washington."

I also learn that at Rio Grande, New Jersey, their results this year surpass those of last year, for they report that the sorghum which on the 26th of August in 1883 gave a juice of 7½ deg. Beaume, and 8 per cent polarization; this year upon the 24th of August gave 10 deg. Beaume and 14 per cent by polarization.

Last year the Rio Grande people told me that they used Dr. Collier's reports on sorghum as their text-books, and had confirmed his results in their own practice. I see also that even Massachusetts has offered a bounty for sorghum sugar. This seems the "unkindest cut of all" for Doctor Loring, who, while laboring to prevent any appropriation for sorghum experiments by Congress, was unable to turn his attention to Massachusetts, but perhaps they felt justified, since I see by the report of the Mississippi Valley Cane Growers' Association (p. 59) that Henry B. Blackwell, Director of the Maine Beet Sugar Co., in a letter, says: "I have recently become convinced by the experiments of Professor Collier, of the U. S. Department of Agriculture at Washington, D. C., that the juice of well-matured sorghum is equal to that of the sugarcane." And he reports as follows concerning some cane (sorghum) of his own raising in Boston: That "the juice was analyzed by Prof. S. P. Sharpless, State Assayer, 114, State-st., Boston, with the following results:—"

| | Per cent. |
|-----------------------|-----------|
| Cane sugar | 18.00 |
| Inverted sugar | 2.09 |
| Ash | .89 |
| Gum | .84 |
| Water | 78.18 |
| | 100.00 |

PROF. SAMUEL JOHNSON, of the Michigan State Agricultural College, has published his report on experiments with ensilage, in which he takes strong ground in its favor, but without putting forth any argument or visionary claims in its behalf. He says:

"I am confirmed in the belief that three tons of the ensilage is equal in feeding value to one ton of hay. The yield of ensilage corn was eighteen tons per acre, equivalent in a feeding value, in a combined ration, to six tons of hay. Ensilage means the growing of an equivalent to 6 or 10 tons of hay per acre. Admit, only, that three pounds of ensilage will take the place of one pound of hay, in a mixed cattle ration, even then if animals fed with it thrive, are healthy, and present a general appearance much like that resulting from grass feeding, coming out, after four or five month's confinement, with sleek coats with not much, if any, loss of weight, and with no more shrinkage of milk yield than we ought reasonably to expect as the time from calving increases, we must conclude that there is some virtue in fodder prepared in this manner. Claim only this, and is it not a profitable and a practical method of securing large yields of corn, sorghum, and other forage crops, and preparing them for convenient and economical feeding?"

"It is to be regretted that so many extravagant statements have been made in relation to the value of ensilage—the number of cattle that could be kept from the product of a single acre, &c. Practical, thinking men have been deterred from investigating this subject and giving it such attention as it really deserves, because of the wild statements of impractical enthusiasts.

"I am more than ever convinced that the idea I suggested two years ago, that ensilage will prove a cheap substitute for roots, will be approved by any farmer who will make the trial. Farmers who have had experience in feeding stock know how desirable it is to have some succulent food as a part ration at least, during our long, cold winters. Roots are a desirable cattle food, but an expensive crop for the average farmer to raise and handle. But few farmers have the facilities for storing them in any quantity. They must be buried in the field; and in the winter, with the thermometer below zero, digging out the roots and getting them to the stock is not a desirable task. If ensilage will give us the succulent food at less cost, in shape to be easily handled and occupying but a small space in storage, it must prove of value. What are the farmers in Michigan to do with the coarse fodder raised on our farms, but to feed them. They are too bulky to transport to market—they must help to make beef and mutton, but the farmer needs something to feed in connection with them to make them of more value, and the ensilage will help out in this direction.

"The large number of silos erected during the last year in all parts of our country indicates that ensilage has the sanction of a number of our leading farmers, and that actual tests confirm

reasonable claims as to its value as a cattle food. The farmers of Great Britain, too, are greatly interested in this subject, and it has received the favorable attention of some of the leading English agriculturists."

MR. GEORGE FRY, F.L.S., the well-known chemist, who has been associated with Mr. Ekman in so many valuable and important discoveries, has addressed himself to the scientific study of ensilage, and in the following letter to the *Agricultural Gazette* he explains why the fermentation which takes place in the fodder stored in the silos not only does not render it rotten and unfit for food, but positively makes it more digestible; and as this problem has doubtless puzzled many amongst our readers who have given attention to the subject, they will be glad to know that it has been solved to the satisfaction of so high an authority as Mr. Fry:—

As the nature of the fermentation in silos and the cause of the extraordinary preservation of their contents are little understood, I take the liberty of calling the attention of your readers to some observations which I made this summer on the temperature of ensilage during its first fermentation, with the hope that others who possess silos will make and publish similar observations.

In order that the conditions may be clearly understood, I may mention that my silo consists of a range of three, each 12 feet square and 15 feet deep, of an estimated capacity of at least 50 tons of ensilage each. They have solid walls, 9 inches thick, of Portland cement concrete, and the bottoms are of the same material; 9 feet 6 inches of the walls are above ground, and 5 feet 6 inches under ground. On the front side each silo has a door of red fir 2 inches in thickness, which is closed and made secure before the filling of the silo is commenced. The silos are filled from the top.

The green crop is mown, carried at once from the field, and pitched from the cart into the silo, where it is spread as evenly as possible, and is well trodden, especially round the edges.

The silo is not filled up at once, but a fresh layer of fodder about 2 feet thick is put in every day (as recommended by M. Goffart). When the ensilage begins to reach the top of the silo, the mass sinks considerably in twenty-four hours, so that complete filling is a work of some days.

The filling of No. 1 silo was commenced on June 7, 1883, with trifolium incarnatum, of which about 15 tons were put in; then about 3 tons of rough grass, then another ton of trifolium, filling up with clover and rye-grass. On June 30 the silo was full.

By means of a perforated iron tube with a sharp steel point, driven into the centre of the mass, I ascertained the temperature to be on June 30, at 2 feet from the top surface 31½° C.; at 3 feet, 43½° C.; at 4 feet, 46° C.; at 5 feet, 53° C.; at 6 feet, 56° C.

This silo was then covered with paper, and with 2 inch planks laid closely together, sand being thrown on to the planks to the depth of about 12 inches.

On July 11 the mass had sunk about 6 feet; it was, therefore, uncovered, and the temperature at 6 feet from the surface found to be 60° C. The silo was filled up with meadow grass, covered, and weighted as before.

The operation of uncovering and filling up with meadow grass was repeated on July 17, and this silo was finally closed and weighted with 2 feet of sand on July, 21, when I ascertained the temperature at 6 feet from the surface to be still 60° C.

The filling of No. 2 silo was commenced on June 30, with clover and rye-grass, and proceeded somewhat more rapidly than that of No. 1. When the height reached was 9 feet from the bottom, I ascertained the temperature at 6 feet from the surface to be 36° C. After this, meadow grass of good quality was put into this silo. On July 7, the temperature at 6 feet from the surface had risen to 65° C. On July 14, it was again uncovered (having sunk fully 6 feet), and the temperature then, at 6 feet from the surface, was 70° C.

From these observations it will be evident that the temperature in the interior of these silos was maintained for a very considerable period at from 60° C. to 70° C. (=from

140° to 158° Fahr.) The escape of heat from so dense a mass is very slow. On July 1, the temperature of the sand covering No. 1 silo was 20° C., and on July 7, it had risen to 30° C. only.

I may remind your readers that Pasteur found that if wine, of a quality very liable to acetous and other injurious fermentation, were raised (in cask or bottle) to a temperature exceeding 50° C., the vitality of the germs of fermentation was destroyed, and the soundness of the wine (if preserved from contact with the atmosphere) was in all such cases maintained. (*Vide* "Etudes sur le Vin, par M. L. Pasteur. Paris: 1866.") It appears to me that what I have stated above is sufficient to account for the preservation of the ensilage. The oxygen contained in and among the green herbage is sufficient, in the beginning, to excite a brisk fermentation (probably of a complex character); but the silos being air-tight, and the mass, walls and covering bad conductors of heat, the temperature soon rises above 50° C., the oxygen is replaced by carbonic acid, the fermentation is arrested, and the ferment destroyed by the high temperature. Thenceforward, as long as the silo is maintained hermetically sealed, the ensilage is preserved.

It will not be surprising if green food, which has been exposed for weeks to a temperature of 60° to 70° C. (140° to 158° Fahr.) should be rendered more digestible by cattle.

THE following Sorghum notes are by J. N. Muncey, Iowa Agricultural College, September 11, 1883:—Crushed 5,852 pounds green cane, from which 201 pounds of syrup boiled down to 232 degrees Fahrenheit was made. With the present facilities for crushing the cane we do not get to exceed 30 per cent of the juice, being required to run the crushers too rapidly. September 15, from 170 gallons of juice from cane greatly damaged by the frost, we manufactured 135 pounds of syrup boiled down to 40 degrees Beaume. The cane raised in the college grounds and by farmers near Ames is of an inferior quality, and has been damaged by the frost. The per cent of sucrose or crystallizable sugar the syrup contains has not yet been determined. The State appropriation was not sufficient to purchase all machinery necessary for practical experiments, and consequently little is to be expected from this institution. As Dr. E. L. Sturtevant says, "An appropriation sufficient to insure an attempt at experiments, and yet insufficient to make an attempt successful, is one of the best ways to kill any interest in experimental station work that I can recommend." More details of the work will be given your readers in the future.

In this connection, let me mention to those anticipating entering into the sorghum business, to so arrange their defecators and evaporators that they may be easily separated from the condensed steam-pipe in the fall when through using them. If the coils are of iron, it will be almost impossible to have each pipe in the pan so level that in freezing they will not break.* If the pans are disconnected from other pipes and allowed to drain perfectly, no trouble will follow, and the apparatus is ready for another year's work. This is mentioned as an expensive blunder that every beginner need not make.

A DESPATCH from Washington, says the *Farmer's Review*, announces that the commission already provided for to make a thorough investigation of the extent of the existence of trichina in the hogs of this country, will soon be appointed by the Commissioner of Agriculture, and will enter actively upon its work. Its mission will not be so much to ascertain the percentage of hogs infested with this dangerous parasite, as the districts from which the diseased hogs come, and to discover the causes and remedy, if one can be found.

Prof. Ditmar, of the department, has already been spending some time in Chicago in preliminary work, in the effort to determine the proportion of diseased hogs killed in this city, and has already made his first report based on the examination of a few hundreds only. On this basis he finds about 4 per cent have trichina, which corresponds with the results reported by Mr. Billings, of Boston, who made examination of the flesh of 8,773 hogs, between 1879 and 1881.

The examinations of American pork conducted under the direction of the French Government and covering more than a

million pieces, showed that but 2 per cent contained trichina, which is about the percentage found among the native German swine, although the German Government has made the charge that American pork is diseased the pretext for excluding it from the markets of that country; while, as a matter of fact, as shown by official examination, it is as free from the disease as its own home product. It is believed that, with examinations conducted in this country on as large a scale as in Europe, the percentage here would not exceed that shown by the examination of American meats in Europe; the smaller number of examinations giving a higher percentage than when conducted on a larger scale.

An important admission is made by Professor Ballinger, one of the best authorities in Europe, in a work recently published, who says: "From numerous examinations of American hams, the trichina has been found uniformly dead. The entire importations of Paris failed to reveal one case of infection." There is no doubt that the disease, though still existing, is on the decrease. Dr. Salmon, veterinary of the Department of Agriculture, states that in former years it could be found in 8 per cent of our hogs. But while it exists at all, it is prejudicial to our American pork in the markets of Europe, as also to some extent lessening consumption in this country; and the farmers should be found ready, in their own interests, to co-operate heartily with the Commission in any measures which may be found practical to utterly exterminate the disease in this country, if such a thing is possible, and thus remove the chief obstacle to the free movement of our hog products to the markets of Europe, and at the same time increase their consumption at home.

THE following resolution has been communicated to all Collectors in the Madras Presidency:—"Village officers should be ordered to report at once to tahsildars the appearance of any locusts in the village; tahsildars will in turn report to divisional officers without delay. The breeding season of the locust appears to be (at least in the Bombay Presidency) the months of May and June. It is therefore in the months of August and September that the young locusts, hatched from the eggs of any locusts that may have alighted in a village during the preceding six months, may be looked for, and it is while they are young, and cannot fly that they should be destroyed by every means in the power of the villagers. Nothing appears to be more successful at that stage than the Cyprus screen supplemented by pits."

AN interesting catalogue of Agricultural implements and machines, says the *Civil and Military Gazette*, which have been tried in India, has been published by the Agricultural Department of the Government of India. The list is supposed to give only those that have been found efficient and useful; but out of the 83 implements or machines regarding which reports have been received—though this number can hardly exhaust the list—Mr. Buck is compelled to admit that only a few—about a dozen—have found favour with native agriculturists; whilst it is only in regard to the Biheea sugar-mill that he is able to record a "real success." Its use is established in Bengal, and is extending everywhere. It is a remarkable fact that of all the ploughs, winnowers, &c., the introduction of which into Indian agriculture has been the aim of Agricultural Departments and model farms, for many years past, only this simple substitute for the Indian *kolhu* should have been accepted by the ryot. Cheap ploughs he does not care for, expensive ploughs he cannot afford; whilst labour-saving machinery is of little value to the cultivator, who carries out his agricultural operations, throughout the year, with little addition to the labour procurable in his own family. It is equally remarkable that indigo planters—who are the only persons who work the land on any large scale, and can afford to expend capital in so doing—have done little or nothing to introduce and popularise agricultural implements amongst the poorer tillers of the soil. The success, however, of the Biheea mill proves that when any machine is forthcoming, which really supplies a want, the Indian agriculturist is not backward in availing himself of it. These mills are sold by thousands annually; whilst the Kaiser plough, to which is given, as is rational, the place of honour in

Mr. Buck's list, makes no real progress in the estimation of the ryot. The plough is bought, indeed, but has taken no hold on the mind of the cultivator. The old excuses are still made for throwing aside a plough which has been bought to please the *Sahib*; and it will be many years before these prejudices are overcome. The same obstacles stand in way of the more general adoption of the Swedish plough, which finds favour with the authorities of the Saidapet farm, Madras; whilst the more expensive ploughs of English make, by Ransome, Howard, Collins and Co., the prices of which run up to fifty or sixty rupees, if bought at all, are carefully preserved, to be brought out at each successive Agricultural Exhibition, where they of course receive prizes, and where their owner is as regularly praised for his enterprise in furthering the improvement of agricultural knowledge. There is, perhaps, a future for an improved water-lift. Pumps are "enquired for"—to use the commercial phrase; and those on the McCornas principle appear likely to satisfy a want, and replace the ordinary rope and basket, where water is fairly near the surface, or the basket-lift on canals.

THE *Rangoon Gazette* says:—"In British Burmah we have fortunately but little to fear from the dreadful scourge of famine, but the consequences of a failure of our rice crop would undoubtedly be very serious indeed;—so much so that the reading of the reports for the past few weeks cannot but have excited feelings of grave anxiety. Although we annually export quantities of other merchandise, these are mainly the produce of Upper Burmah, and if our paddy crop failed our export business would be practically annihilated, whilst the sale of imports would be at a standstill, the people having no money to make purchases. Our merchants, therefore, must have felt serious misgivings at the unexpected cessation of the rains which appeared everywhere to be over for the season. The matter cannot have been viewed with any less anxiety by the Government, for a bad harvest would undoubtedly have been productive of great trouble for the Executive. The cultivators, unable to repay their loans, and with no money to make their ordinary purchases, would have become turbulent and unmanageable; crime would have enormously increased; and revenue would have been difficult to collect. Fortunately, refreshing rain fell in the Rangoon district during the past week, and it was the hope of every one that other districts had been equally favoured. On Friday night we made enquiry from the Director of Agriculture, but found that no special means were being taken to ascertain if the much needed showers had been general throughout the province. The matter appeared to us to be of so much importance that we telegraphed to the Deputy Commissioners in charge of the principal paddy districts, and we have to thank these gentlemen for the promptness and courtesy with which they have replied to our enquiries. Their reports, of which our readers have the benefit to-day, are of course a week later than those published in the official *Gazette*; and a comparison will show that they represent matter in a much more favourable light,—so much so, indeed, that, in conjunction with the fact that the weather continues showery, they are calculated, in great measure, if not entirely, to remove the anxieties which have been felt during past week or two; and we may look forward to an average harvest if not an abundant one. Mr. Ireland's message from Pegu is specially cheering; the bounty of nature which brings prosperity to his district should make it less difficult to manage, and we may hope the Sittang Railway will be open in time to benefit by the traffic in grain. We telegraphed to his neighbour in Shwagyreen, but have not yet had a reply, no doubt in consequence of the incomplete arrangements of the Telegraph Department. Ma-co-bin, the head-quarters of the Thonegwa District, is not yet accessible by rail, so that from these two important paddy districts we have no report; but from their position we may expect that they also have been favoured with rain. As to Hanthawaddy, the Deputy Commissioner informs us by letter that "the rain that has fallen these past few days has been general throughout the district, and it is reported to have benefited the crops, which promise well."

A CONTEMPORARY says:—"The advantages of deep ploughing, in resisting the effects of drought, are so fully acknowledged, that it is a matter of wonder why the intelligent *Jats* cultivators of Northern India do not adopt improved ploughs more readily. It is not altogether from the want of information; for energetic district officers have been known to carry about a Kaiser plough (made at the Cawnpore Farm), and to hold small ploughing exhibitions at each halt. The matter becomes of renewed interest in view of a somewhat deficient rainfall; and it would be a decided step in the right direction, if the advantages of deep ploughing for tap-rooted plants were brought fully home to the ryot. The cultivators of the Madras Presidency, even, are not so backward as their Northern brethren; and have bought, and used, large numbers of improved ploughs, the lowest price of which is Rs. 16. It cannot be the case that the cattle of Northern India are unable to drag the new ploughs, for they are certainly superior to those of Madras; it is probably a strong conservative feeling—as difficult to stir as the under-strata of their own soil—which keeps the *Jats* to the use of the mis-called ploughs, of a design centuries old. There is, it is true, some doubt, even yet, as to which plough is the best of the many inventions recently brought before the ryot at agricultural shows: the Kaiser of Cawnpore, the Ryot, the Nawab, the McGregor, or the heavier Swedish ploughs so much in favour in the Madras Saidapet Farm. It is not every plough that will suit every soil; but the plain fact that crops in a deeply-stirred soil have larger resources of plant-food, and therefore, greater resisting power against drought, ought to be hammered into the ryot's mind till he acknowledges and acts upon it."

THERE is really nothing of much moment to note in the Report on the Cawnpore Experimental Farm for the *rabt* season 1882-83. The Director of Agriculture and Commerce, N.-W. P. and Oudh, in submitting Major Pitcher's report to the Secretary of the Government of the Province, has nothing to say that is not said quite as well in the report itself. The Director believes he has of "struck it" in nitrogen. Only he speaks of it with becoming caution and reservation. "For the production of cereals nitrogen is the one great want of soils like that of the farm," Major Pitcher says: "it will be interesting to note as time goes on how far potassic nitrate alone, unaided by cinereal (or mineral) manures, will suffice to maintain fertility. The use of nitrous earth as a manure is freely resorted to by native cultivators in the shape of a top-dressing to poppy, tobacco, wheat, jetia sawam, and sometimes I believe to maize." Mr. Warrington writes: "As the whole object of artificial manuring is to supplement the deficiencies of the soil, it is highly desirable that a farmer should ascertain by trials in the field what is the actual amount of increase which he obtains from the manure he purchases. A few carefully made experiments will teach him what his land and crop are really in need of. Should he add superphosphate with the nitrate of sodium for his wheat? What dressing of the nitrate is most economical? Is superphosphate alone sufficient for his turnip crop, or should guano or nitrate be employed as well? What is the smallest quantity of superphosphate sufficient for the crop? Will it pay to use potassium salts for his seeds or pasture? These and many other questions can only be answered by trials on his own fields, and on the farmer's knowledge of such facts will depend the economy with which he is able to use purchased manures."

This extract, Major Pitcher says, explains in clear language what we are attempting to do at the farm, *viz.*, to arrive by degrees at some sort of estimate as to how far the wheat crops of these provinces may be benefited by the application of manures which will pay for their purchase, at the same time maintaining fertility, and not simply exhausting it. Variations will be made as experience suggests. For instance, we are now able to see pretty clearly how useless the application of calcic sulphate by itself is for a cereal crop, though the addition of it to farmyard manure appears to produce some increase in the effect of the latter, owing no doubt to its converting part of the insoluble nitrogenous humus into soluble ammonia compounds.

OFFICIAL PAPERS.

ACT NO. XIX. OF 1883.

THE following Act of the Governor-General of India in Council received the assent of his Excellency the Governor-General on the 12th October, 1883 :—

An Act to consolidate and amend the law relating to loans of money by the Government for agricultural improvements.

WHEREAS it is expedient to consolidate and amend the law relating to loans of money by the Government for agricultural improvements ; It is hereby enacted as follows :—

1. (1) This Act may be called the Land Improvement Loans Act, 1883.

(2) It extends to the whole of British India, but shall not come into force in any part of British India until such date as the Local Government, with the previous sanction of the Governor-General in Council, may, by notification in the local official Gazette, appoint in this behalf.

2. (1) The Land Improvement Act, 1871, and Act XXI of 1876 (an Act to amend the Land Improvement Act, 1871,) shall, except as regards the recovery of advances made before this Act comes into force and costs incurred by the Government in respect of such advances, be repealed.

(2) When in any Act, Regulation or notification, passed or issued before this Act comes into force, reference is made to either of those Acts, the reference shall, so far as may be practicable, be read as applying to this Act or the corresponding part of this Act.

(3) In this Act, "Collector" means the Collector of land revenue of a district, or the Deputy Commissioner, or any officer empowered by the Local Government by name or by virtue of his office to discharge the functions of a Collector under this Act.

4. (1) Subject to such rules as may be made under section ten, loans may be granted under this Act, by such officer as may, from time to time, be empowered in this behalf by the Local Government, for the purpose of making any improvement to any person having a right to make that improvement, or, with the consent of that person, to any other person.

(2) "Improvement" means any work which adds to the letting value of land, and includes the following, namely :—

(a) the construction of wells, tanks and other works for the storage, supply or distribution of water for the purposes of agriculture, or for the use of men and cattle employed in agriculture ;

(b) the preparation of land for irrigation ;

(c) the drainage, reclamation from rivers or other waters, or protection from floods or from erosion or other damage by water, of land used for agricultural purposes or waste-land which is culturable ;

(d) the reclamation, clearance, enclosure or permanent improvement of land for agricultural purposes ;

(e) the renewal or reconstruction of any of the foregoing works, or alterations therein or additions thereto ; and

(f) such other works as the Local Government, with the previous sanction of the Governor-General in Council, may from time to time, by notification in the local official Gazette, declare to be improvements for the purposes of this Act.

5. (1) When an application for a loan is made under this Act, the officer to whom the application is made may, if it is, in his opinion, expedient that public notice be given of the application, publish a notice, in such manner as the Local Government may, from time to time, direct, calling upon all persons objecting to the loan to appear before him at a time and place fixed therein and submit their objections.

(2) The officer shall consider every objection submitted under sub-section (1), and make an order in writing either admitting or overruling it :

Provided that, when the question raised by an objection is, in the opinion of the officer, one of such a nature that it cannot be satisfactorily decided except by a Civil Court, he shall postpone his proceedings on the application until the question has been so decided.

6. (1) Every loan granted under this Act shall be made repayable by instalments (in the form of an annuity or otherwise), within such period from the date of the actual advance of the loan, or, when the loan is advanced in instalments, from the date of the actual advance of the last instalment, as may, from time to time, be fixed by the rules made under this Act.

(2) The period fixed as aforesaid shall not ordinarily exceed thirty-five years.

(3) The Local Government and Governor-General in Council in making and sanctioning the rules fixing the period, shall, in considering whether the period should extend to thirty-five years or whether it should extend beyond thirty-five years, have regard to the durability of the work for the purpose of which the loan is granted, and to the expediency of the cost of the work being paid by the generation of persons who will immediately benefit by the work.

7. (1) Subject to such rules as may be made under section ten, all loans granted under this Act, all interest (if any) chargeable thereon, and costs (if any) incurred in making the same, shall, when they become due, be recoverable by the Collector in all or any of the following modes, namely :—

(a) from the borrower—as if they were arrears of land revenue due by him ;

(b) from his surety (if any)—as if they were arrears of land revenue due by him ;

(c) out of the land for the benefit of which the loan has been granted—as if they were arrears of land revenue due in respect of that land ;

(d) out of the property comprised in the collateral security (if any)—according to the procedure for the realisation of land revenue by the sale of immovable property other than the land on which that revenue is due :

Provided that no proceeding in respect of any land under clause (c) shall affect any interest in that land which existed before the date of the order granting the loan, other than the interest of the borrower, and of mortgagees of, or persons having charges on, that interest, and, where the loan is granted under section four with the consent of another person, the interest of that person, and of mortgagees of, or persons having charges, on that interest.

(2) When any sum due on account of any such loan, interest or costs is paid to the Collector by a surety or an owner of property comprised in any collateral security, or is recovered under sub-section (1) by the Collector from a surety or out of any such property, the Collector shall, on the application of the surety or the owner of that property (as the case may be), recover that sum on his behalf from the borrower, or out of the land for the benefit of which the loan has been granted in manner provided by sub-section (1).

(3) It shall be in the discretion of a Collector acting under this section to determine the order in which he will resort to the various modes of recovery permitted by it.

8. A written order under the hand of an officer empowered to make loans under this Act granting a loan to, or with the consent of, a person mentioned therein, for the purpose of carrying out a work described therein, for the benefit of land specified therein, shall, for the purposes of this Act, be conclusive evidence—

(a) that the work described is an improvement within the meaning of this Act ;

(b) that the person mentioned had at the date of the order a right to make such an improvement ; and

(c) that the improvement is one benefiting the land specified.

9. When a loan is made under this Act to the members of a village community or to any other persons on such terms that all of them are jointly and severally bound to the Government for the payment of the whole amount payable in respect thereof, and a statement showing the portion of that amount which as among themselves each is bound to contribute is entered upon the order granting the loan, and is signed by each of them and by the officer making the order, that statement shall be conclusive evidence of the portion of that amount which as among themselves each of those persons is bound to contribute.

10. The Local Government, with the previous sanction of the Governor-General in Council, may, from time to time, by notification in the local official Gazette, make rules consistent with this Act to provide for the following matters, namely :—

(a) the manner of making applications for loans ;

(b) the officers by whom loans may be granted ;

(c) the manner of conducting inquiries relative to applications for loans, and the powers to be exercised by officers conducting those inquiries ;

(d) the nature of the security to be taken for the due application and repayment of the money, the rate of interest at which, and the conditions under which, loans may be granted, and the manner and time of granting loans ;

(e) the inspection of works for which loans have been granted ;

(f) the instalments by which, and the mode in which, loans, the interest to be charged on them, and costs incurred in the making thereof, shall be paid ;

(g) the manner of keeping and auditing the accounts of the expenditure of loans and of the payments made in respect of the same ; and

(h) all other matters pertaining to the working of the Act.

11. When land is improved with the aid of a loan granted under this Act, the increase in value derived from the improvement shall not be taken into account in revising the assessment of land-revenue on the land :

Provided as follows :—

(1) Where the improvement consists of the reclamation of waste-land, or of the irrigation of land assessed at unirrigated rates, the increase may be so taken into account after the expiration of such period as may be fixed by rules to be framed by the Local Government with the approval of the Governor-General in Council.

(2) Nothing in this section shall entitle any to call in question any assessment of land revenue otherwise than as it might have been called in question if this Act had not been passed.

12. (1) In the Indian Registration Act, 1877, section 17, clause (b), for the word "certificates" the words "orders granting loans" shall be substituted.

(2) In the same Act, section 58, for the words "a certificate" the words "an order" shall be substituted.

(3) In the same Act, section 89, first clause:—

(a) for the words "a certificate" the words "a loan," and
(b) for the words "such certificate" the words "his order," shall be substituted.

SELECTIONS.

VETERINARY SCIENCE IN INDIA.

THE October number of the *Quarterly Journal of Veterinary Science in India and Army Animal Management* contains, as its leading article, a review of the past year's efforts to obtain a proper footing for the Indian veterinary surgeon, as well as an epitome of the principal events of the year connected with veterinary science. The editors have "every reason to believe that arrangements are pending for relieving us from a threatened decrease in numbers, and a consequent imposition of duties which it would have been impossible to perform with even an approach to efficiency." It is also stated that there is "reason to believe that some such Civil Veterinary Department as we have persistently advocated is in course of preparation by the authorities." Education, we are told, has much progressed during the past year, which is remarkable for the graduation of the first batch of native practitioners educated at Lahore, and now diplomated as Veterinary Assistants. There is a probability of a Veterinary College being established at Calcutta soon. "In Madras also the standard of Veterinary education at Agricultural Schools has been raised, and Veterinary pupils have been rendered eligible for certain important appointments under Government, such as the Inspectorship of cattle and sanitary posts in the city." The writer arrives at the conclusion that "it is in the direction of education that the greatest advances have been made during the past year." He does not forget to record the fact that "for the first time in history has a British decoration been conferred on a Veterinary Surgeon." We concede to our contemporary all the credit, and more which is claimed for its efforts during the first year of its existence and hope it may long continue to assist in extending a knowledge of veterinary science in this country. In No. 5, now before us, Mr. S. Gillespie, V. S., A. V. D., Kurrachee, gives the details of a case of dilatation of the stomach. Some practical observations on tetanus in India are made by Mr. Gerald H. Fenton, V. S., 3rd Light Cavalry. After detailing some of the cases he has had to deal with, Mr. Fenton says he can "add nothing to the generally accepted view that nature must practically be left to her unaided efforts in tetanus, except that experiments made by me confirm the view that the paroxysms of tetanus are controlled by chloroform, and the question naturally arises whether, if we could keep a tetanic patient under anæsthetic influence for a prolonged period, the tetanus would not of its own accord pass away, without fatally exhausting the patient as it usually does. In the absence of paroxysms nutritive and cathartic treatment might be adopted with some chance of success." Further on, Mr. Fenton states that "the treatment recommended in all but our standard professional works errs on the side of fussiness; the only chance of cure is to keep the patient quiet." Speaking of the true nature of tetanus he calls it a symptom of disease, rather than a disease, because tetanic spasm may be due to many pathological states. "Altogether practical observation seems to confirm the view that in traumatic cases the theory of entanglement of the ultimate nerve fibres is the most feasible which has been suggested, although it hardly seems sufficient to account for the occurrence of tetanus where no wound is present." Some useful hints in connection with "Shying in Horses," are offered by Mr. D. C. Pallin, V. S., A. V. D., 14th Hussars. According to his experience, this dangerous habit is met with more frequently in India than at home. He writes:—

Experience teaches us that shying is a 'vice' in very many cases attributable to skittishness, nervousness, or simply habit; and when a horse which does not generally shy is found to do so, we ought always to look to the state of the harness in order to make sure that nothing is wrong there. Thus the blinkers may be smaller than the animal is accustomed to, or they may be so arranged on the head straps that the animal can see imperfectly over them. Also the driver may have something to do with shying; thus if he nervously prepares to prevent the horse from swerving at a suspicious looking object, the animal will probably think that he is required to shy and do so accordingly, the best treatment for this form of shying is to give the driver a good stiff 'peg.' In cases of skittishness, the best plan is to give the animal plenty of regular work; and, however badly the vice may be shown at starting, it will be found much less marked after he has settled down to work and finds he has something else to do than make a fool of himself. When nervousness is the cause, as it is most often in mares, which (I fancy) shy much more frequently than stallions or geldings, it is necessary to coax the animal as much as possible—to spare the whip or spur and make much of her. Different horses swerve to or from the object which frightens them, most try to get as distant from it as possible, the others of their disturbance being fear. This plainly shows that we ought to try in every possible way to familiarize him with the appearance of objects, to quickly and gradually work him so near that he can smell, touch, or see distinctly whatever has been the object of apprehension. In this way only can a nervous horse be cured of shying.

Mr. T. J. Symonds, V. S., 1st Madras Light Cavalry, continues his paper on the grasses of the Madras Presidency. He is one of the most productive of the contributors to the journal, for besides the paper mentioned above, he gives a short paper on the Amrut Mahal Cattle Breeding Establishment. Other papers discuss veterinary details, and make up a journal of which the "vets" of India may well be proud.—*Madras Mail*.

DAIRY MANAGEMENT AT BOTHERHAMSTED.

SIR JOHN B. LAWES contributes an interesting paper on dairy matters to an American contemporary, from which we extract the following:—

At Botherhamsted the herd goes into the fields of permanent pasture about the middle of May, and remains out about six months. The cows come in to be milked twice a day. In addition to the pasture they receive dehydrated cotton cake, varying in amount from 4 lbs. per cow to very much less, the quantity allotted to each cow being in proportion to the amount of milk she is giving. Although we have carried out so many experiments at Botherhamsted upon oxen, sheep, and pigs, we have never attempted the dairy, and I am inclined to think that it would be almost impossible to arrange a series of experiments which could not be open to objection. My dairy, therefore, has never been subjected to a rigid scientific investigation, and the statistics I shall bring forward are merely those taken in the ordinary way.

The cows are kept under cover for about six months, and are tied up in pairs—forty in one house and about ten in another. The urine runs into a large underground tank, from which, when full, it is carried on to the pasture by a water cart. The food of the cows varies with their condition, and the more milk they are giving the higher they are fed; but when dry, or nearly so, they have only roots and hay or straw, unless it is decided not to keep them for the purposes of the dairy, in which case they are milked and fattened at the same time. When fat they sell for about 150 dols. The following is the amount of food consumed by the cows while in the stalls:—

| | | Tons short. |
|------------------------|-----|-------------|
| Cotton cake | ... | 13 |
| Barley meal | ... | 11½ |
| Bran | ... | 10½ |
| Chaff (½ hay, ½ straw) | ... | 70 |
| Mangels, pulped | ... | 224 |

In addition to this, 13 tons of cotton cake are used during the summer. It is somewhat difficult to estimate the number of acres of pasture used by this herd, as the cows have the first run of the grass, and the coarser and rougher part of the pasture is fed by other stock. Possibly each cow may consume the produce of 1½ acre.

In the winter months the milk sells for about 22 cents per gallon, a price which is hardly more than sufficient to cover the cost of the food and attendance, so that the dairy does not often get back more than the manure free of cost. The annual expense of labour upon a cow amounts to about 13 dols.

It is probable that ensilage as a substitute for roots will be fairly tried in this country during the winter. The experiments which have been published both in the States and in Canada appear to show that ensilage is inferior to roots as a food for milking-cows. Still in the United States, where a crop like corn is available for the purpose, and where great difficulties exist in the production of roots, ensilage may prove of much value, while it may be but of little value under the different conditions that prevail in England. Roots are our cleansing crop, but rye—which would probably be the crop most suitable for ensilage—is not a cleansing crop like corn.

A dairy cannot be carried on with profit unless a supply of some succulent food is available for winter consumption. In the proximity of towns, brewers' grains are largely employed for this purpose; but the cost of carriage confines their use to localities not far removed from the place of production. At the present time I find no food so suitable for our purposes as mangels. The course I pursue is to manure highly, but not to aim at getting large roots. The plants are thinned out to stand 1 foot apart from each other, with a space of 27 inches between the rows, and the produce amounts to from 20 to 30 tons per acre.

The success of a dairy depends very much upon individual attention to the animals. A cow that is not a good milker should be fattened or sold. The food should also be regulated by the milk-producing powers of the cow, and as the milk declines the more costly food should be reduced. Special care should also be taken that the cows are thoroughly milked, as a careless milker will sometimes not draw more than half the milk that the animal is capable of yielding.

The diet of a cow when yielding milk should contain more nitrogen than the diet of a fattening animal, as milk contains more nitrogen—in proportion of its other constituents—than the increase of a fattening animal. A fattening animal also increases with tolerable regularity throughout the whole period in proportion to its weight. But with the cow the process is totally different, as it may commence by giving from 3 to 4 gallons of milk per day for some time, and end by giving none. Four gallons of milk per day would in a week amount to 28 gallons, which would contain 35 pounds of dry substance. A fattening cow would not, in the same time, increase more than 15 or 16 pounds, of which amount not much more than one-half would be dry matter. As, further, the nitrogen contained in the milk would be from six to seven times as much as the amount of nitrogen contained in the meat, it is evident that the regulation of the food of a cow to its varying

condition in regard to its milk supply, constitutes a most important item in the economy of a dairy.

The amount of nitrogen contained in cotton cake differs but little from the amount of that substance contained in dry milk—which is about 6 per cent. In bran it is about 4 per cent; in barley, 2 per cent; in dry Mangels also about 2 per cent., and in hay and straw, 1 per cent, and $\frac{1}{2}$ per cent respectively. It is evident, therefore, that by increasing and diminishing the three former foods, the requirements of the animal in the various stages—ranging from the time of its yielding an abundant supply of milk to when it becomes absolutely dry—can be fully met.

The actual amount of dry matter consumed daily by the herd, during the six months of winter, amounts to about 31 pounds per head; but, as I said before, the quality and quantity of food are regulated by the milking properties of the particular animal.

RED CLOVER.

SIR J. B. LAURE has the following article on red clover in the *Agricultural Gazette* :—

Any one who walks over a field of red clover soon after it has been mown, may observe how rapidly fresh growth in the crop takes place. In twenty-four hours, and probably within even a shorter period, a leaf of considerable size has sprung up. This growth arises from matter stored up in the root; and it is in connection with this store of matter that I now propose to make a few observations.

In our ordinary four-course rotation experiments commenced in 1848. After taking a clover crop in 1850, beans were substituted in their place until the year 1874, when clover was again grown, and the crop was repeated in 1882.

In our rotation crops there are altogether six experiments. On two the roots are very highly manured; on two they receive superphosphate of lime; the other two experiments are left wholly unmanured. On three of the experiments the whole of the roots, as well as all the other crops grown, are carried off, and on the other three they are fed on the land. It is evident, therefore, that when the crop of clover was grown in 1874, the land of the six experiments was in very different states of fertility. From one of the unmanured plots twenty-six crops had been carried off, and in 1882 this removal had increased to thirty-four crops. Both in 1874 and in 1882 the plant of clover was good upon all the experimental plots. In 1874 the clover was mown twice. As the first crop is cut about fourteen months after the seed is sown, and the second only about two months later, under ordinary circumstances the first crop is very much the larger of the two. This rule holds good on all the highly-manured experiments in both years, and it also holds good in three out of the four superphosphate experiments, but it fails in the 1882 crop, where the roots were carted off, and it also fails on all the unmanured experiments of both years.

If we take the highly manured turnips which were fed on the land in 1874 as representing the soil in the highest condition of the series and assume the first crop of clover hay to be 100, the second crop would be represented by 40. But at the other end of the scale where no manure had been applied and all the product had been removed for thirty-four years, assuming the first crop to be 100, the second crop is represented by 233! The second crop is in fact considerably more than twice the weight of the first crop, and the regularity with which the relation between the two varies in proportion to the food at their disposal, precludes the idea of this large excess in the weight of the second crop being accidental.

I do not propose to offer any explanation of this very curious property of the plant, but merely to point out that many of our agricultural operations are so conducted as to produce an unnatural growth. The natural tendency of the clover is to produce seed, and our large crops of clover are little more than stem and leaf. With abundance of manure, succulent growth of some kind is not difficult to obtain, as may be seen in the gigantic roots exhibited at agricultural shows. But on the other hand, it is very easy to overgrow, more especially when the production of ripe seed is the object; and with our fluctuating seasons it is by no means easy to attain the happy medium which on the one side is bounded by too little and on the other by too much.

On our unmanured rotation the first crop of the clover hay only weighed 7 cwt. per acre, but the plant was perfectly good. It is evident therefore that clover sickness is not altogether due to poverty of soil. No doubt the mild winters of 1873-4 and of 1881-2 were favourable to the underground growth of the plant. That there is a great deal still to be learnt in regard to the properties of the leguminous plants will, I think, be at once evident when I mention that at Rothamsted several of these plants—including tares, sainfoin, Lucerne, and Bokhara clover—are now growing luxuriantly in a field which has long ceased to grow red clover.

In a paper read by Dr. Gilbert at Montreal last autumn, and recently published in London by Messrs. Harrison, St. Martin's-lane, he shows that the first 9 inches of a garden soil, which has grown clover for many years, has lost very large amounts of nitrogen; while, on the other hand, the surface soil of a field which had grown barley followed by red clover had gained nitrogen, as compared with a portion of the field which had grown two crops of barley; and this notwithstanding the fact that the clover removed from the soil much more nitrogen than the barley! Nor was this all, as the barley that followed the clover was far superior to that which followed barley! How, then, are these two conflicting results to be reconciled? If clover were again sown with the barley it would be almost sure to fail; while the clover in the garden soil still continues to flourish most luxuriantly, although it

has been grown there for nearly thirty years in succession! Are we to suppose that the clover in the garden soil finding all the nitrogen it required close to the surface was not compelled to look for it lower down in the subsoil? It is possible that such may be the case.

A still more remarkable experience, however, in regard to red clover has yet to be recorded. Since 1848 we have attempted to grow continuous bean crops, but comparatively with but little success. It is true that the crops have not altogether failed, as was the case with the red clover—but we have not been able to grow continuously good agricultural crops by means of manure; and for the last two or three years no crop whatever has been grown, as though grass seeds were sown last autumn they entirely failed. During the spring, the soil in various places was sampled to a very great depth, and barley and red clover were sown. I was prepared for an indifferent crop of barley, as the partial analysis of the soil and subsoil showed that the amount of nitric acid they contained was small, but—I was going to say I was surprised; this would, however, not be correct, as nothing with regard to red clover could surprise me—I will say therefore that I have been much struck by the great luxuriance of the clover which has just been cut with the barley. Even upon the bean land which has received no manure since 1848, and where the beans did not exceed a few inches in height, the clover is most luxuriant, while the colour of the leaf is of a rich dark green such as I have hardly ever seen before.

At the present moment we have therefore the following problems requiring explanation—(1) Red clover growing for thirty years upon an unmanured garden soil; (2) Red clover refusing to grow on land where four or five leguminous plants are flourishing with the greatest luxuriance; (3) Red clover growing with great luxuriance where beans refuse to grow at all; (4) Red clover removing large quantities of the nitrogen of the surface soil of the garden. (5) Red clover increasing the nitrogen of the surface soil when grown on the farm land.

There is one very important fact, at all events, that the experience of forty years has taught us, and that is, that plants are endowed with number of remarkable properties, which are only brought out when they are placed in circumstances where they can be observed.

NOTES ON POULTRY KEEPING.

FIRST and foremost among the different species of the animal kingdom submitted to the caprice and dominion of man, none have shown themselves so rich in variety as the different races of fowls. They have been produced in hundreds of forms and colours, without any discredit to either of them, because all these varieties have their relative merits. Naturalists acknowledge nine sorts or races of fowls, which it will be useless to enumerate, the object of these notes being to point out to farmers and cottagers those most suitable for stock, so as to derive a profit commensurate with the undertaking.

We know nothing of the origin of the fowl; but we suppose the parent stock to come from the jungles of India, and we must take it that all the races of birds created by the different crossings had their origin from thence. As stock birds, we should advise farmers to obtain the following:—Leghorns, Hamburgs, Game, Dorking, Spanish, Houdan, Crèvecoeur, Brahmas, Cochins, and Dominiques—this last is an American bird.

Many opinions have been expressed by fanciers of poultry as to what breeds are considered the most useful in a marketable point of view. Doubtless we have gone through a 'poultry mania,' the aim of which has been to breed for feather, and to produce a perfect animal in all points, and most seductive to the eye, the real and valuable point being lost, viz., the rearing of poultry as producers, both for eggs and as articles of consumption. To rear birds exclusively for the show pen is an expensive pleasure, for it requires a good purse to maintain such a fancy. Poultry bred under such circumstances, and treated with the utmost care and trouble, like exotic plants, must be kept warm, without being exposed to the sun's rays for fear of spoiling their feather or faces; they are daintily fed, and at the least sign of indisposition; the chemist's shop is ransacked to find antidotes to all their ills; should they have a delicate plumage, they are at times washed and dried with the greatest care; finally, natural food not being sufficient, condiments are added to force their energies, &c., &c. We maintain that poultry thus reared are useless as stock birds on a farm.

The above-named races of birds have been increased and multiplied so much that we can only, in our present notes, speak of a few prominent and profitable breeds, advantageous on account of being good layers and first-class table birds. This is a great consideration in selecting stock.

From experience we can say that the 'Brahma' has been found a most useful bird indeed, either for pure bred stock or for crossing. They lay well in winter, are good sitters and careful mothers and will bring up early chickens with little trouble; they seldom wander from home and are too heavy to fly, but care must be taken that they are not fed too exclusively on maize, as it produces much inside fat, and like many other breeds, the laying is impeded.

The 'Houdan,' one of the French breeds, cannot be spoken of too highly, both for laying and meat-producing qualities. Their eggs are large and white. They are reared without difficulty, and feather easily and early. Their plumage is usually white, with black spangles. They have a fine crest, a top-knot, particularly the hens, and the comb of the cock is very handsome, having what is called the strawberry leaf shape. Beyond their usefulness, they are very attractive on a farm, and make a fine show. At four months old the pullets will weigh from 4 lbs. to 4½ lbs., and the cockerel from 6 lbs. to 7 lbs. The flesh is remarkably white and

delicate, and there is less waste of offal. The bones are particularly light. They have five toes like the Dorking; the legs white with the exception of a few black splashes. These birds are hardy, and are more easily raised than any other French breed. They do not wander, and are much less destructive. The greater part of these crossed with the Brahma make magnificent specimens, imparting to the Asiatic breed its delicate flesh and large full breast. Mr. Lewis Wright, the eminent writer on poultry, particularly recommends the cross of the Brahma and Houdan, that is, a Houdan cock and Brahma hen.

The Crèvecoeur comes next. This is another of the French breeds. A large, square-built bird, well set on short firm legs, full breast, limbs well developed, four toes, legs black, carriage upright and proud, is even more precocious than the Houdan, and as he is a larger bird, his flesh is more abundant, so that at the same age he weighs more than the last named kind. His plumage is entirely of a lustrous metallic black. The cock has a fine crest, inclined to fall backwards, with a comb in the shape of two horns, —that of the hen much smaller in proportion; but the crest is fuller, and stands erect. They produce certainly the most excellent poultry seen in the Paris market. Their bones weigh even less than those of the Houdan; the flesh is short, fine and white; and they fatten easily. Indeed, if well fed in the yard, they do not require to be put in the fattening pen at all, and at six months they are like young turkeys for size. The pullets are of an unheard-of precocity, as they can be put up to fatten at two and-a-half to three months old, and at the end of a fortnight are ready to kill. This is perhaps the best breed for crossing, and experience has proved that, crossed with a Brahma hen and Crèvecoeur cock, the produce is large, hardy, and magnificent birds, and as a cross have been sold at 7s. 6d. each, and many more could have been disposed of could they have been had. Therefore this breed can always be strongly recommended, and will prove remunerative in a commercial point of view, as the cockerels can be disposed of at from three to four months old, and the pullets not required for laying, even earlier. The eggs are white, and very large.

The 'La Flèche' is another of the French breeds, and a most wonderful bird it is for size and delicacy, often weighing from 8 to 10 lbs., a bird much prized in France; but as it does not thrive well in this climate, we would not recommend it to farmers, especially so far north.

The 'Spanish.'—We presume from the name that the bird is a native of Spain. Be that as it may, we are satisfied that this breed is necessary on a farm where eggs form part of the staple commodity, and crossing brought to a good issue. The Spanish is a fine large bird, strong and hardy when fully developed, but delicate to rear, as the chickens feather tardily, and are subject to scoup through the inclemencies of our climate; therefore great care is required that they should be warmly housed until they get their feathers. In general, Spanish are never bred too early in the year. Their plumage is deep black, with glossy reflections. Legs blue or dark lead colour. The comb in both sexes must be large, but in the cock it is perfectly upright, separated, and extending from the base at the upper mandible to the back of the head; that of the hen, when fully developed falls completely over on one side. This bird is remarkable for its white face, which should extend over the eye as far as the comb, and reaching down to the wattles. To be perfect, the face ought to be of a pure white, without wrinkles, and soft and smooth as chamois leather. The eggs are white and large, and the hen of this breed is considered to be very prolific. It will be as well not to give too many hens to a Spanish cock; four are quite as many as he can manage.

A Brahma hen and Spanish cock produce a capital cross, what is called 'Cuckoo,' some with white legs, some with yellow, and we fail to see a difference between this cross and Dominiques and Plymouth Rocks. However, these crosses thrive wonderfully well, and at three months are almost double the size of their congeners of the pure breed. C. W.

THE POULTRY OF THE FARM.

THE next matter to be considered in poultry-keeping is the housing, and this is a very simple affair; still there are many incidents to be noticed, and for which provision must be made. Next to food, the housing of poultry is very important, and the two combined form the secret of poultry farming with advantage.

Poultry-houses, that is, roosting and laying houses, are made with very cheap materials, and can be thatched or tiled; for a cold country we should advise thatch, as being warmer in winter, and cooler in summer. Let ventilators be made all round the building, which can be opened or shut according to the season.

The roosting house must be so prepared that perches can be placed in amphitheatre style, so that those breeds which perch high may avail themselves of the highest positions, whilst the heavy birds such as the Asiatic breeds perch low, and can be easily accommodated; besides, the perches thus made prevent the fowls from dropping their dirt on one another. To keep the roosting house as clean as possible place under each perch a thin plank covered with dust or ashes, so that the droppings can be collected with ease and secured in a barrel, and which can be disposed of at any time by use or by sale. In the laying house use small boxes in tiers for the nests, not too high, or the birds would not be able to reach them. On the upper tiers use a small landing board at the entrance, so as to prevent the fowls entering the nest too abruptly, otherwise they run the risk of breaking the eggs should there be any in the nest.

On the top of these boxes a shelf can be fixed from one end to the other, on which small round baskets can be placed, lined with hay or cut straw, so as to induce the fowls to lay in them,

for fowls are such capricious creatures that very often they will not enter a box that has been made for them to lay in, but will rather go and seek out a nest for themselves. These baskets on the shelf are a great inducement, and they often take to them in preference to any other. However, it is better to adopt any plan than to allow your hens to steal their nests, and thus lose the eggs.

We are just entering upon a season when new laid eggs are in great request, and all poultry farmers ought to adopt the means to promote their production, and it would amply pay those persons who give special attention to it.

At this time of the year all pullets hatched in March and April should be well housed, with a south aspect as much as possible, and well sheltered from the north and east winds.

The floor of the house should be covered with dry leaves, which are easily obtainable at this period of the year, or with the hull of corn.

Fowls delight to scratch in this and pick out the corn that may be thrown to them, for nothing keeps poultry in health so much as moving about and having plenty of exercise.

The ventilators during the cold weather should be shut.

A dry soil is indispensable for egg production, therefore the poultry yard should have from time to time a layer of the soil taken up and used in the kitchen garden, and replaced by a layer of gravel or ballast, so laid down that the rain water may easily drain off.

In addition to the fowl house, it is very advisable to have an open shed, for fowls require to live in the open air as much as possible, and the only object of the shed is to replace the large trees under which fowls in summer take refuge from the rain and sun. The shed can be used in summer as a roosting house, with the addition of a few perches. Dry leaves or the hull of corn should also be thrown into the shed, and the base of the shed bordered up by a plank, so as to prevent the fowls from scattering it abroad.

A supper of boiled potatoes, well mashed up, and mixed with middlings, will do sometimes; at others, all sorts of vegetables, boiled up and mixed with scraps of meat and fat. In Scotland, where oatmeal is cheap, it would form an excellent food. All these ingredients must be given warm.

In the morning, give them wheat, oats, buckwheat, and sometimes a little hemp seed, but sparingly. Barley and oats, half boiled, are very exciting, and good for the laying. Be particular and give them good and clean water. Change the hay or straw of the nests often, and have a care how the eggs are handled, for in winter the shell is very thin.

With the above precautions, farmers ought to have plenty of early eggs which would find an easy and remunerative market.—C. W.—*North British Agriculturist*.

POULTRY IN INDIA.

POULTRY are entitled to a fairly prominent place among our food supplies. The Indian *murgh*, however, cannot hold a candle to the produce of our fowl-yards in England, although the parent stock of all those magnificent birds came originally from Asia. It was only in 1847 that any keen interest was felt in England and America in improving the domestic fowls. Many of our readers will remember the excitement caused by the introduction of the Coochin Chinese: they are justly entitled to be called "the parents of poultry fancy." Previous to their advent there were few who cared for keeping fowls; indeed it was looked upon as a harmless mania, much the same as the keeping of white mice. Within the last ten or twelve years, a greater interest has been developed in improving our Indian poultry-yards. People have begun to find out that by a small outlay and a little care an egg superior to that laid by the country hen and a finer bird than the *murgh* for the table can be procured. It is true that the climate of the plains is somewhat against us in many parts of India, but it has been proved that the English varieties can be made to succeed if proper precautions are taken. The improvements that have so far been developed are due to the energies of a few who have taken the trouble and gone to the expense of importing superior stock: these have by degrees been spread throughout the country. Ten or twelve years ago it was a rare thing to come across English fowls but now in fifty per cent of the poultry-yards either half-breeds or pure breeds will be found. After the first outlay in purchasing the birds the cost is very much the same, whatever kinds are kept; the English ones will, it is true, eat a little more, but they give a better return in larger eggs and more meat. Houdans, Bemas, Coochins, &c., are now really within the reach of all. From two to ten rupees is the price ordinarily asked for birds according to their size and purity of breed, and it takes a very short time for them well to repay the purchaser the money he has laid out. Importation is a more serious matter. It is no use getting out any but birds of high class strains; but these may be got on an average for a sovereign a piece. Carriage by sea or land is an expensive item. Allowing for deaths, agency fees, and remuneration to the ship's butcher who looks after them on the way out, half-a-dozen birds could not be landed at a station far from the coast much under two hundred rupees. Though it appears a large sum, the investor may with ordinary luck recoup himself in a year, and have a balance to profit and a well stocked yard. The only place, we believe, where poultry-farming has been carried on on a large scale is at the Chowkorie poultry yards near Almora, at an elevation of over 6,000 feet. It has proved successful. The proprietor has found no difficulty in disposing of as many young fowls as he can produce from his French Houdans at Rs. 30 a trio. Imported birds do better (as is but natural) in the hills, the climate being more suited to them. They are less liable to degenerate, and the young

stock is more robust. It would almost pay residents in the plains better to purchase fowls bred from imported birds in the hills than to get them out direct from England.

Houdans and Bramas (light and dark) appear to be the varieties very generally selected by importers. The former takes its name from a district in France, and is of modern origin, having been first described in 1865. It is, however, a very characteristic breed. The birds may be recognised at once by their triple comb, full-crest whiskers and beard, black-and-white-spangled plumage, and five toes, the two hind ones being one above the other. It is worthy of note to show how breeds are made up to suit the requirements of judges at poultry shows, that the original Houdans had scarcely any beards or whiskers, and the fifth toe was uncertain. Houdans are non-sitters, and lay large white eggs; the chickens are very precocious, and if properly fed are fit for the table at four months.

The origin of the Brama is not quite so clear. They first appeared as a distinct breed in 1846 in America, and were said to have been brought over by a sailor who obtained them at Lakhimpore, on the banks of the Brahmaputra river. There was a long and bitter controversy as to where they first came from; some asserted Chittagong, others Shanghai; indeed for a long time they were called grey Shanghais. One thing is certain—we cannot now find fowls answering to their description about the Brahmaputra, or we should not send all the way to England for them. This breed thrives in India and is more hardy than the Houdan. Their propensity to sit interferes a great deal with the production of eggs; they make excellent table birds if properly fattened. They are magnificent fowls to look at, with their heavily-feathered legs and stately carriage. A good Brama cock will scale 12 to 14 pounds. An excellent cross may be obtained by mating a Brama hen with a Houdan cock. The progeny are almost invariably black with crests, and are non-sitters.

The great thing to guard against is degeneration. Poultry seem to be more liable to it in India than in Europe. It is attributable to three causes: climate, bad feeding, and breeding in and from limited stock. In importing fowls it is advisable to order, say, three cocks from different yards and three or four hens. Mate the hens with one cock; put the pullets reared with No. 2, and so on with No. 3. In this way three strains can be established, and the breed will be kept up to the mark of the original stock many years if otherwise properly treated.

Artificial incubation has made great progress in the last two or three years, and it greatly simplifies the production of a large number of chickens. Mr. Thomas Christy, of Fenchurch-street may be justly called the pioneer of the hydro-incubators in England (though, as is known to most people, the hatching of eggs by artificial heat dates back to the times of the ancient Egyptians). But last year a great advance was made in the invention by Mr. C. Hearson of an automatic incubator, which regulates the heat of the egg-drawer of itself. No changing of water or circulating boilers are required. A small lamp (kept constantly burning) is connected with a flue through the tank, and arranged so as to heat the water. The following is the way in which the heat in the drawer is regulated. On a little stand over the eggs, and near the bottom of the tank, is a capsule of thin brass, enclosed in which are twenty drops of a liquid which boils at the temperature at which the egg-drawer is to be kept. A piece of stiff wire stands in the centre of the capsule, and is connected with a light lever at the top of the machine, at the other end of which hangs a damper over the lamp chimney. When the drawer is underheated, the damper closes the chimney and all the heat goes into the tank. When the proper temperature has been arrived at, the capsule boils, swells, acts on the lever, raises the damper, and allows the heat to escape from the lamp instead of acting upon the water. If a greater heat is required, a small weight which is on the lever is moved forward, when greater pressure will be required to raise the damper. The arrangements also for keeping a current of damp air over the eggs are simple and thoroughly efficient, only necessitating the addition of a little lukewarm water about once a fortnight. Taken altogether this incubator may be said to give a minimum of trouble and a maximum result. Like all new patents it had but a short reign in its entirety. Mr. Christy at first scoffed at it, but soon found that his old style of incubators were being thrown out of sale, and therefore he had to provide something like Mr. Hearson's champion incubator, but sufficiently different not to infringe the patent. He calls his "the thermos-tatic incubator." None of these have, as far as we know, found their way to India, but there are a few of Hearson's working very successfully. Those who may get them out should be provided also with a "foster-mother," in which 50 or 60 chickens can be reared with great ease. The general mistake made in bringing up chickens is that they are entirely trusted to the tender mercies of the "marghi-walla," and in consequence they are not only underfed, but badly fed and grow up stunted and degenerate fowls. Everything depends on the treatment for the first two or three months. Constant feeding with good food and frequent change of diet will reward the rearer amply, and give him in return birds as good as those that come out from England.

Considering the number of poultry fanciers there are now in India and the difficulties that exist in getting fresh stock, we would suggest the formation of a poultry club. By means of this, the members would be enabled to exchange birds and get in fresh strains, and to join together for purposes of importation. It would give an impetus to poultry-farming for pleasure and for profit, and enable many who do not know now where to get good fowls at a moderate price to supply their wants.

It has been satisfactorily proved that eggs for setting cannot be trusted to the post-office. In almost every instance parcels containing eggs have reached their destination with the yolks broken and unfit for incubation. Taken by hand with ordinary care they

may be transported from one end of India to another, and be found fit for setting at the end of the journey.

Before leaving the subject it is worth noting that a great many eggs might be saved for household purposes which are left to rot under the hen by testing them after they have been five or six days incubated. They are quite fit then for cooking, and will be found very little inferior to fresh eggs. Testing is simple. Light a lamp or candle; put it in a box with a round hole in front of the light, and one at the top to let off the heated air; make, in a piece of black card-board or tin, a hole the shape of an egg; in one hand hold the egg and in the other the card-board in front of the light the whole of the interior of the egg will be visible. If fertile, the vein will be distinctly looking like a spider; if unfertile, the appearance will be the same as that of a fresh egg. Remove all these and send them to the kitchen for use. If two hens are set at the same time and many unfertile eggs are found, the remainder can go under one hen, and a fresh lot be started under the other; much waste of labour being saved. The hen won't mind the extra six days; she careth not for time. The American saying about an unpunctual man is "he has no more idea of time than a sitting hen,"—*Pioneer*.

VEGETABLE EXTRACTS.

WHILST it is admitted on all hands that the cultivation of economic plants, yielding sugar, fibres, and drugs, and their by-products of all kinds, according to the climates and soils suitable to their cultivation, might be profitable, the obstacle that the grower and the capitalist alike have had to face, has been the almost insuperable difficulty of extracting the several products at a cost of production that will leave a profit at all commensurate with the risk incurred. When we take into account the amount of unprofitable vegetable matter associated with the more valuable part of the plants to be dealt with, the cost of labour and the carriage of the crude material to the nearest mill and the comparatively poor results, the costly and by no means perfect machines return upon the outlay, we are the less surprised to find how quickly the enthusiasm of the most hopeful is cooled after the first or second essay in any of these directions.

The efforts made by the Government of India to improve the condition of the fibre producers, who had expended large sums in cultivating 'china grass,' affords us a capital illustration. Their evident desire to promote on a larger scale the cultivation of plants which from time immemorial had produced valuable fibres for native textile fabrics, led the Indian Government to offer a prize of some five thousand pounds sterling for the production of a suitable machine to remove the fibre from the woody matter associated with it, in the *Bassia* plant particularly. It was in the year 1870 the offer was made. The machine was to be of such a character that it could be used in the rainy season, when the plant was still green, at a time when the difficulties of heating the plants are insuperable except by artificial means. The first trial was made at Saharanpore in 1872. The results obtained were considered unsatisfactory; but Messrs. D. and J. Greig received a prize of £1,500 for a crushing machine then shown. The trials were postponed for some years, and at the second contest in 1880, no less than twenty-three competitors presented themselves. The ruling idea was a crushing machine. Exhibitors from England, America, France, Denmark, Hungary, Java, New Zealand, and India were represented, but in no case could a machine be found that would "extract the fibre from the brown exterior pellicle and from the excess of agglutinative gummy matter which holds them together in such a manner as to produce an article whose value in London shall not be less than £45, and of which the cost of production shall not exceed £15 per ton of fibre obtained." Crushed stems, in fact, no matter how deftly treated by mechanical means, refuse to surrender their more delicate filaments (and these are the most prized), and only give up their coarser constituents, in a more or less mangled form, when subjected to the clumsy ordeal they have undergone. All at once, and that not so very long ago, the chemists who had been investigating the progressive action of fermentation in plants in cold and warm water, obtained a clue to the laws which seem to regulate the process of vegetable decomposition, and did not fail to observe that as the temperature was raised, the adherence of the internal ligenous part and the cortical envelope is destroyed, and the separation of each of the different concentric layers which form the wrapper, is effected. The fibre-bearing plant is provided with three zones in the bark, consisting of the epidermis and a thick layer of parenchyma, which contains the chlorophyllum of the plant, then a larger layer of cortical fibres, generally isolated and independent of each other; the last zone is contiguous to the cambium in which are the finer fibres and associated with these there is an abundance of small crystals of carbonate of lime; it was found, that if the stems were subjected to superheated steam or some such calorific agent, the moisture could be drawn off effectually in a few minutes by the addition of some chemical re-agent, and the fibres extracted free from any kind of adhesive particles that would render it unsaleable, there was an end to all obnoxious or tedious "retting" or "stripping" processes and the object of their search was attained. During the last four years steady progress has been made in rendering the operation perfect and profitable, and at a cost which will be hardly felt when the value of the fibre comes to be submitted to the manufacturer; similar experiments have been made in England, France, and America. The work commenced in France by the well-known M. A. Favier has been improved upon by the chemist M. Fremy. In England much attention has been bestowed upon the subject, whilst American chemists have contributed their share. Side by side with these discoveries of such incalculable

value to the commerce of the future, chemists in the north of Europe, in America, France, and England, were making equally rapid progress in perfecting new methods of extracting saccharine matter from sugar-cane, sorghum and maize plants. The old and cumbersome process of extracting sugar from cane by elaborate and costly machinery, always most profitable to the manufacturer, but which after all gave only a poor return to the grower, had this effect amongst others, that the production of beet-root and other kindred saccharine plants upon the market in competition with our colonial trade, was admitted on all hands to be defective and unprofitable. Other means have now been found by which pure sugar and syrup can be drawn direct from the sugar-producing plants we have indicated. By this new departure costly machinery is dispensed with, and the land in some instances, without overtaxing its power of production, can be made to give a continuous yield of sugar-producing plants. Crushed cane with its poor return in sugar, molasses, and treacle will become things of the past. The American Department of Agriculture, ably supported by chemists of known experience, have superintended for the last four years the new method of extracting sugar by a simple chemical operation, and at a cost which, including the cultivation of the plants, at first sight may seem simply incredible, until the tables of expenditure and profit are consulted, when all doubts are dispelled by the evidence they contribute. It appears by the published report of the United States Department of Agriculture at Washington that—"Eighty batches of syrup taken by the manager from the finisher in the consecutive order of production made from cane and stems of all conditions, good, bad, and indifferent, show an average of 66 per cent of crystallized sugar. Several of the best show as high as 80 per cent. All would have shown this high average if all the cane had been good." In England like results have been arrived at as we have already shown in the pages of this journal, and it is possible when the researches now under observation and exhaustive trial have been perfected, as they assuredly will be before long, that a perfect revolution in sugar production will be effected. Nor has the investigation of methods for extracting these products by chemical means limited the field of operation; these same chemical studies have led to others of equally high commercial importance. The same or equally simple methods will be applied to the extraction of dye stuffs and other alkaloids with apparatus, which, we gather, is of the simplest and most inexpensive character.

SUGAR MAKING AT CHAMPAIGN, ILLINOIS.

THE marked success that last year attended the production of sugar from the sorghum canes at Champaign, Ill., and Rio Grande, N. J., awakened a deep and wide spread interest throughout the country. It seemed to give promise of such an ultimate development of this industry as would free us from dependence upon foreign sources of supply which now furnish nine-tenths of the sweets consumed in this country, and cost us annually in first cost and duties paid upon the same, nearly \$150,000,000. While for some years the quality of syrups from sorghum, under improved methods of manufacture, have steadily improved till many manufacturers now furnish syrups of excellent quality, and while from time to time quantities of sugar have been produced from the unexpected and unwished for granulation of syrups, no direct efforts at sugar production can be claimed to have been successful and profitable till those of last year at Champaign and Rio Grande. While the juices of the sorghum canes, as shown by analysis, were known to be rich in true cane sugar, the practical difficulty has been to obtain it in a crystallized form, and in paying quantity. There were hindrances to crystallization not till recently understood, nor the methods for overcoming them. But since the work was so successfully carried on last year at the above named points, and both companies are now, together with several new ones in different parts of the country, engaged in successful sugar production from this season's crop of cane, it can, we think, be safely claimed that sugar production from sorghum is now established as a sure, certain and profitable manufacturing industry, which offers as profitable employment for capital as any other manufacturing industry in the country. A recent visit to the works of the Champaign Sugar Manufacturing Company, enables the writer to give to the readers of the *Farmer's Review* many facts of interest in regard to this season's work. The company has this year 615 acres of cane, while last year it had but about 250. Its quality is better than last year, August and September furnishing a great deal of sunshine, which is needed to develop the sugar in the juices of the growing and ripening cane. Some fields of cane have been frosted so as to make it unprofitable to work for sugar, but without materially injuring it for syrup. But the most of the crop is in good condition for sugar making. About 100 acres of the cane was grown by the company, the balance by farmers on contract, the company paying \$2.50 per ton for cane delivered at the mill, topped but not stripped. The average yield is about 2 tons per acre. A good deal of improvement has been made in the machinery of the works since last season. Then there was a deficiency in boiler capacity, in charcoal filters, in defecating capacity, and in centrifugals, so that while the mill could grind 180 tons of cane per day and the vacuum pan finish the juice into sugar, they were enabled to run only about 80 tons per day. Now they run about 150 tons every twenty-four hours, the deficiencies that existed last year having been fully supplied. They use a double-roller mill (No. 1 Cuba flexible). The rolls, three to each set, are 4 feet in length by 30 inches in diameter. The power is so ample that with cane fed solidly from four to six inches deep, there is no clogging or check to the motion, which is 22 feet per minute. The second set of rolls is about 12 feet beyond the first, a carrier taking the partly pressed cane from the first to the second. On its

passage it is moistened by jets of hot water from a perforated horizontal pipe some two feet above the carrier. The second pressure is immense. The bagasse mostly comes through entirely separated at the joints.

What is not so separated is thrown back, to come through again, by a boy stationed at the tail end of the second set of rolls. The company claim that by the use of this second set they save at least fifteen per cent of juice that would be lost if only a single mill was used. Last year the firing under the boilers was by coal alone, and men and teams were employed to cart the bagasse away to get rid of it. Now it is all used as fuel, and supplies two-thirds of all the fuel required, taking the place of fifteen tons of coal per day. It is carried by the bagasse carrier over the front end of the furnaces, and by an ingenious arrangement of slides, fed directly into shafts running down into each of the four furnaces. No handling of it is required, only the manipulation of the slides by cords and pulleys so that each of the four furnaces shall be alternately fed. There is no trouble in keeping the steam up to any desired pressure, and the saving in fuel and labor from this use of the bagasse cannot fall much short of \$80 every twenty-four hours. The juice from the mills flows into a tank from which it is pumped into the juice tank at the extreme top of the building. Here it is treated to lime to neutralize the acid and then drawn off to the defecating tanks, a half story below. These are of galvanized iron in wooden frames and supplied with steam coils. The juice is brought quickly to a boil and the scum taken off. This flows through pipes to a tank on the ground outside the building and is taken away for feeding hogs. The defecated juice next passes to the evaporator of copper, circular, eight feet in diameter and three feet deep, the bottom covered with two inch copper coils. Here it is reduced to 20° Baume, when it is drawn off into settling tanks. When sufficiently cooled it passes to the bone-black filters, up-right cylinders of boiler iron, 18 feet in depth and filled with finely pulverized bone charcoal. From the bottom of the filters the clear, amber-colored, semi-syrup flows into a tank from which it is pumped to reservoirs above the vacuum pan, into which it is drawn as needed. In boiling in the vacuum pan a small amount only is first let in and boiled at a temperature of 170°, till crystals can be seen to be forming freely. This can be ascertained by drawing out a small amount, spreading it upon glass and holding it between the observer and the light, when the crystals can be clearly seen. Additional quantities of the semi-syrup are let in from time to time until at the end of about five hours the pan is full of the boiling sugar, when the *strife* is made. The contents of the pan are discharged into crystallizing wagons—tanks of boiler iron five feet long, three wide and two deep, on iron trucks. These are wheeled into the crystallizing room, which is kept at a temperature of 90 degrees, where the crystallization is perfected. When ready for the centrifugals the wagons are run out and their contents dumped into the mixer, a long horizontal trough, in which a horizontal shaft with wooden arms revolves, which thoroughly mixes the mush sugar. From this it is drawn directly into the centrifugals on the floor below. These are perforated brass cylinders suspended at the end of a perpendicular shaft, which makes 1,200 revolutions per minute. The perforated brass cylinders revolve inside of stationary iron ones. As soon as started the centrifugal force throws the mush sugar against the inside of the perforated brass. The molasses is thrown out through the perforations, while the crystals are retained inside. The molasses is retained by the outside stationary cylinder, and runs off to tanks through a pipe in the bottom. When sufficiently purged the machine is stopped, the sugar adhering to the inside of the brass cylinder is scraped off and discharged from the bottom into a box below, from which it is barreled, and is then ready for market. The sugar thus obtained is called *firsts*. The molasses is afterward reboiled for sugar, and yields in seconds about one-quarter the quantity of the *firsts*. The sugar grades from Yellow C to off A, and finds ready sale at an average of 7 cents per pound wholesale. The molasses remaining after working for seconds is refined, making an article of table syrup, which sells at 40 cents per gallon wholesale, though this price was shaded a little on some lots last season.—*Farmer's Review*.

AGRI-HORTICULTURAL SOCIETIES.

IN the Resolution of the 17th September 1879, it was decided that as grants-in-aid to agri-horticultural societies had been made a charge on provincial funds, the control over such grants should be transferred to local Governments. At the same time it was suggested that donations from the public funds should be governed by certain fixed principles, such as the extent to which the operations of the societies promote objects of public benefit, and the amount of the income derived by them from independent sources. The Government of India also desired to be furnished once every three years, with a progress report, showing the work accomplished by each society, and the help afforded from provincial funds.

The first triennial reports have now been received, and afford the following information. There are, or rather were, agri-horticultural societies at Calcutta, Madras, Lahore, Nagpore, and Rangoon; those at Lahore and Nagpore have, under recent arrangements made by the local Governments, received a new organisation under which they will no longer be known by their former title.

The society at Lahore had long been on the decline owing to a variety of causes. The great difficulty of securing a permanent Honorary Secretary, with sufficient leisure to devote to the proper working of the society, and the greater advantages and facilities afforded to contributors of information by the periodical press of late years, had with other things combined to create a lack of interest in its members. The original objects of the society were imperfectly carried out, and its gardens had gradually assumed the character of a mere agency for supplying seeds and plants.

The condition at which the society had arrived is clearly set forth in a joint report submitted in March last by Major Waco, Commissioner of Settlements and Agriculture, and Mr. Baden-Powell, the Honorary Secretary. On the recommendation of these officers, the Government of the Punjab has decided that the institution shall in future be known as the Government Agri-horticultural Gardens, Lahore, and managed by a committee composed of *ex-officio* and nominated members. The present grant of Rs. 9,000 per annum is to be continued, but its expenditure will be subjected to the control of the Commissioner of Agriculture. Subscriptions will be received as heretofore, but subscribers will not be entitled to more than the full value of their subscriptions in seeds and plants. With the object of securing scientific supervision and advice, it is further intended that with the permission of the Government of the North-Western Provinces and Oudh, the Superintendent of the Botanical Gardens at Saharunpore should inspect the Lahore gardens at stated periods every year. The school for the training of gardeners now attached to the gardens is to be maintained and improved.

The Nagpore Society was maintained principally by annual grants from local and provincial funds. In 1881-82 these amounted to Rs. 4,000, against Rs. 373 realised from subscriptions, Rs. 2,700 from sale of produce, Rs. 600 from miscellaneous sources, and Rs. 600 paid by the municipality. The work of the society lay for the most part in the distribution of plants and seeds, of which but a small proportion were new or exotic varieties. No attempt had been made to collect botanical specimens; no proper record appears to have been kept of the results attained in the experimental cultivation of fruit trees, grasses, &c., and the efforts made to disseminate information have been very limited.

Under these circumstances the Chief Commissioner has decided to formally make the gardens a Government institution, which, practically speaking, they have always been, and to place them under the Provincial Department of Agriculture. The existing grants are to be maintained, and the functions of the society will continue to be exercised by the institution which will take its place. It is hoped by this arrangement to secure continuity of work, which has hitherto been impracticable owing to constant changes in the honorary secretaryship of the society, and to bring the institution into closer relation with the district gardens which exist at every head-quarter station.

Among the remaining societies at Calcutta, Madras, and Rangoon, first in order of importance stands the society at Calcutta, whose operations extend to the whole of India. This society receives a grant-in-aid from Government of Rs. 2,400 per annum. The remainder of its total income of Rs. 35,000 consists of Rs. 16,000 received from subscribers and Rs. 17,100 from sales of produce. In 1883 the society numbered 593 members, some of whom are residents of foreign countries. Its work comprises the distribution of plants and seeds to members and the public, the trial and distribution of various indigenous and exotic products, and the rearing of useful plants. The society interchanges plants and seeds with similar bodies in the British colonies and the other provinces of India, and carries on a considerable correspondence regarding the introduction of new staples, field crops, &c. It also publishes a monthly journal of its proceedings, embodying the botanical and agricultural information collected from time to time. Of the subscriptions received from members, the greater part is said to be returned to them in the annual distribution of vegetable and flower seeds, fruit, grafts, publications, &c., and the Secretary represents that an increase of the grant-in-aid from Government would enable it to perform a larger amount of useful work for the public at large.

The assistance received from Government by the society at Madras amounts to Rs. 3,000 per annum, besides a special grant of Rs. 500 for prizes for useful products. The rest of its income is made up of from Rs. 8,000 to Rs. 10,000 realised from sale of seeds, plants, &c., and between Rs. 2,000 and Rs. 2,500 from subscriptions. A proposal is under the consideration of the local Government to increase the annual grant of Rs. 3,500 to Rs. 4,000 in view of the work done by the society. This consists in introducing, acclimatizing, and distributing plants of known economic value, in making known improved agricultural implements, and in engaging and training gardeners for employment in India and Burmah. Like the Calcutta Society, it publishes periodical reports and any information contributed by its members. It also maintains valuable and extensive botanical gardens, which have recently been enlarged, and afford much interest and instruction to the scientific public and students of various botanical classes. An annual show held by the society is much appreciated by the native public, and serves to interest them in the objects which the association has at heart.

Owing to the smallness of the European community, and the difficulty in obtaining native co-operation, the society at Rangoon has hitherto led a precarious existence. It is almost wholly supported by donations from public funds, *viz.*, Rs. 1,200 per annum from provincial revenues and a similar contribution from the municipality. Rs. 1,600 are obtained from sales of garden produce and some Rs. 700 from members. The objects of the society are the same as those of its contemporaries at Calcutta and Madras, though necessarily conducted on a smaller scale. Efforts are said to have been made in 1881 to induce some Burmese gentlemen to join it as members, and with some small success. In the same year the first step was taken by the Provincial Administration to utilize the society's agency for the promotion of agriculture, by prevailing on the latter to set apart a selected area of the garden for experimental cultivation of crops in which the Agricultural Department is specially interested.

It appears to the Governor-General in Council that, under the circumstances referred to above, the Governments of the Punjab and Central Provinces have acted advisedly in placing

the horticultural gardens at Lahore and Nagpore under the cultural Departments in those provinces. Experience has shown that the communities at those stations possess neither the leisure nor the opportunities and facilities for an effective performance of the duties, which the objects of such societies impose upon their working members. Whilst, therefore, acknowledging the zeal and devotion with which the members of the associations in question have carried out their self-imposed task, the Governor-General agrees with the local Governments that the interests of the gardens will be promoted by the new arrangements which will furnish that continuity of management and direction from the want of which they have hitherto suffered.

Of the great utility of the institutions at Calcutta and Madras there can be no question. At the same time it appears to the Government of India, that the agency afforded by these societies might be more largely utilized by local Governments for the distribution of information, seeds, and plants; for the experimental cultivation of crops; and for various other objects. Where Agricultural Departments exist, the societies might usefully co-operate with them, and the Government grant may appropriately be regulated in view of such co-operation. It seems desirable therefore that in future reports the opinion of the officers in charge of the Agricultural Departments, as to the utility of the societies to the general public, should be recorded. The Government views with favor every endeavour made to enlist the interest and assistance of natives and of agriculturists generally in this work. In this way the value of the societies to the country at large can be greatly increased, and their labors bear permanent fruit. In Rangoon it is observed that these suggestions have to some extent been anticipated, and the Government of India hopes that, working as it does in a comparatively new field and in enjoying other advantages, the society at that station will by the end of the next three years show that it has made full use of its opportunities, and attained an increased measure of usefulness.

THE THEORY OF THE POTATO DISEASE.

RECENTLY in connection with the North of Scotland Horticultural Association at Aberdeen, Mr. Stephen Wilson, of Kilmundy, Aberdeenshire, read an able paper on the above subject. Mr. Wilson proceeded as follows:—There are various diseases which affect various parts of the potato plant; but the disease which is produced by the fungus called *Peronospora infestans* is more especially known as the potato disease; and it is to the theory of this disease that I am to direct your attention. The word 'theory' has sometimes one meaning and sometimes another; what it means here is simply the method or course by which the fungus produces disease in the potato. It will not be possible to go minutely into all parts of the subject, but as I assume to have made a discovery which throws some light upon the true theory, a word or two must first be said on certain points of existing theories of the disease. I scarcely think it is necessary in this part of the country to enter upon any proof that the potato disease is caused by a fungus. Mr. W. G. Smith says in his evidence before the Potato Committee—'Not one potato grower in a hundred knows anything about the exact nature of the potato murrain; the majority of farmers do not know whether the disease is an insect, a fungus, or a gas; whether it is caused by a fog, rain, or a thunder-storm; what it is, whence it comes, or where it goes, they have no idea.' But we shall assume that a knowledge is possessed that the disease is caused by the *Peronospora infestans*. And I think it is of great importance to a clear understanding of our subject that the disease in the tissues and substances of the potato plant should be conceived of quite distinctly from the fungus which produces this disease. The disease is not the fungus, and the fungus is not the disease. If you drive a piece of red-hot iron into your hand, or if you swallow arsenic, disease or disorganization will arise in certain tissues or fluids of your body, but the poison and the iron are not the disease, but the cause of it. And if the *peronospora* is the cause of disease in the tissues and fluids of the potato, the question arises, how does it get into these fluids and tissues? A friend of mine, Mr. Thoms, of Alyth, who has given considerable attention to the potato disease, is of opinion that the *peronospora* arises from pathologically altered cells of the potato itself. But whatever may come out of this view, I do not think that as yet there is sufficient proof of a theory so startling. The views of De Bary, which command a large amount of acquiescence, may be most readily collected from the Potato Blue-book. Mr. De Bary explains these views. He says—'As long as the potato has been in cultivation, I do not know whether there is any evidence that it has ever been free from the potato disease. It is stated by Horsingault, the French chemist, who has lived in South America, that in Western South America, which is the native home of the potato plant, it always is diseased, more or less. And one of the most important points in Mr. Dyer's evidence is the assertion that he has no doubt that the potato tubers carry on the mycelium of the fungus from one year to another. And the way in which he thinks this mycelium in the tubers reproduces the fungus is, that it makes its way up the haulm, probably in some cases growing with the shoots. As the shoots grow up they are always diseased from their infancy onwards, till at last, when the plant is mature, spores are produced and are distributed; and, he adds, there are some facts which tend to show that the mature foliage of the potato lends itself more readily to the attacks of the disease than the young and growing foliage. Then, when the first spores, or conidia, have been produced, it is held that they are dispersed by the wind, and alighting on other leaves, send the tubers or the 300 spores into them, and so spread the fungus and the disease over the whole crop. But it is also held that the fungus not only devastates the foliage, but finds its way down the haulm to the tubers, there being only a modification of the haulm, and

In direct communication with it. These seem to be the more essential points in the theory of De Bary. You see that it affords no explanation at all as to how the fungus first or at any time obtains an entrance into the host plant. If mycelium is lodged in one seed tuber during winter, and works its way up to the foliage, and thus produces disease in a given plant, why does the same principle not apply to all the other plants in a field? One plant is diseased by the action of hibernating mycelium, and another by the action of zoospores. If the first cause is sufficient to produce disease, why introduce the second? The theory of Mr. Worthington & Smith differs somewhat from that of De Bary. The fungus in De Bary's theory can hardly be said to have an existence apart from the host plant; it is a parasite all the year round. It is not producing disease in the plant in autumn. It is lying asleep in the tubers, or at least in some of them. But in Mr. Smith's theory the fungus is not a parasite all the year round; part of its life is non-parasitic, and may be passed within the soil, or upon any substance indifferently. The same mycelium which produces the oidiotyphora is also held to produce resting spores or zoospores, which fall down upon the ground with the dead leaves and branches, and lie in a resting condition till next autumn. When these eggs at length burst, says Mr. Smith, they generally protrude threads which carry seeds or spores, and these seeds are set free in uncountable millions. These seeds sail through the air, and such as fall upon potato plants rapidly gain an entrance to the interior tissues of the host and cause its corrosion and destruction. No doubt, he continues, "living resting spores, together with fungus spawm, are often planted with potatoes, and when this is the case the disease commences with the tuber and works upward; whilst in the former case, i.e., when the germination of the resting spores takes place upon the neighbouring ground, the leaves are the first parts attacked from the air, and the disease works downward to the tuber. It is also a part of Mr. Smith's contention that when the disease is begun by resting spores, it is carried on and augmented by conidia. In this theory, as well as in that of De Bary, you see that there are two principles on which the fungus produces disease in the potato; the action of resting spores and the action of conidia. Both theories make use of the conidia when once they get them. Now it may be asked, if the resting spores, lying as mere non-parasitic fungi upon the ground, can germinate and produce spores, which are the perfect fruit of fungi, what can the peronospora want with the potato? The potato is doing it no harm, and apparently can do it no good; it has perfected its fruit before reaching the potato, so that its attack on the potato seems a piece of pure mischief. But if the spores or conidia produced on the mycelial threads arising directly from resting spores hibernating on the ground, are sufficient to set up disease in a certain number of leaves, why are they held to be insufficient to produce all the disease? One main defect of these theories seems to me to be that they want a philosophy. You do not see that any rational purpose is served by the introduction of the parasite into the host plant. Now, the antecedent probability is certainly very great, that in the case of all parasites, the entrance into a host plant is for some important biological purpose. Many minute fungi, such as *penicillium*, live and perfect themselves by producing reproductive spores or fruit on dead material without entering into living tissues and becoming parasites. And if the *Peronospora infestans*, and many others, could perfect themselves on dead material, there would be no occasion why they should become parasites. But if this *Peronospora* cannot produce its spores or conidia or fruit except by becoming a parasite and feeding upon the substance of a living plant, then we begin to see that there is a philosophy in the potato disease, and that although mischief may result, yet the essential purpose of the parasitism is that the full development of the parasite may be accomplished. The question then comes to be—In what form and in what manner does the *Peronospora* enter into any part of the potato plant? In the last paper which I read to this society on the club-root fungus (*Plasmiodiophora brassicæ*), I endeavoured to show that the germinal form in which the fungus is absorbed by the roots of turnips and other cruciferous plants is a granular plasmodium. And the purpose, so to speak, for which this fungus enters the host plant is that its spores or reproductive elements may be perfected. If it did not enter the host plant it could not reach its full development. Again, in the case of smut, which in some years destroys perhaps five per cent of the oats, especially after turnips, the fungus does not attack the ears from the atmosphere in any form whatever. If you will examine the progress of this fungus, and the disease of the ears consequent upon it, you will find the fungus in its rudimentary stages long before the ears are out of the sheath, or have attained to a length of one-tenth of an inch. And going a little further you may come upon an oat plant, or a barley plant, having six or eight stalks on one stool, and if you find that one ear is smutted, you may predict almost with certainty that the ears of all the stalks are smutted. Now, it is impossible to suppose that this could be the case if the elements of the fungus came through the atmosphere. These elements come in from the soil. The myceliating spores are lying in the soil, but they cannot reproduce perfect smut in the soil; they must in some form enter a host plant, and go through a process of gestation. I may say here that this fungus does not enter the corn plants by the ears, or by the leaves, or by the roots; it enters by the cotyledon or scutellum, which is the organ that absorbs the dissolving body of the grain connected with the seed, and the fungus enters the embryo, mixed up with its proper food, in the granular plasmodium. I have frequently seen this plasmodium which produces it, in the early stages of the germination of the corn plants; and the phenomenon affords the only explanation of the smutting of all the ears upon a stool. Frequently, however, when the attack of smut is severe, several of the tillers on a stool are killed at an early stage, and never go the length of producing ears at all. The roots enter the structure

of the corn plants in exactly the same manner as the smut. They are introduced into the germinating embryo in the form of a plasmodium by the absorptive action of the cotyledon as it draws in the dissolving food of the young plant. Now, accepting these statements for facts, it will be no matter for surprise if we shall find that the elements of the *Peronospora infestans* in a rudimentary form enter some part of the potato plant from the soil, and not from the atmosphere. If the club-root fungus enters the turnip in the form of a granular plasmodium, and goes through a process of growth for the very purpose of perfecting its spores, why may not the potato fungus act upon the same principle? Well, it was from some of these considerations that I was led to examine perfectly fresh potato tubers, perfectly fresh stalks, and perfectly fresh leaves in all stages of their growth; and in all these parts, as well as in plums or fruits, I have found certain small organisms which are distinctly not of the potato disease, but easily separable from them by dissection. I gave the name of sclerotia to these bodies, implying thereby that they are small sclerotia. A fungal sclerotium is in general a solid leathery or horny mass of excessively branching mycelium, all felted together by the fluid which exudes from it. The ergots on many of the grasses are most familiar examples of sclerotia; but there are many other sclerotia besides ergots. They are all the resting or hibernating states of certain fungi. They lie dormant through the winter, and germinate at various periods of the following summer and autumn, producing their appropriate fungi, the spores of which again produce the mycelia from which grow the sclerotia show specimens, and so the life-cycle is completed. Now, supposing that these sclerotia, which are in most cases so abundant in the tissues of the potato plant, possess the functions of sclerotia, the circumstance will be in perfect harmony with that department of fungal life which has just been alluded to. These sclerotia, however, are parasitic; they exist in the tissues of the living plant. They are most perfectly developed in the leaves, and are situated about the middle of the leaf, and over its whole extent. Seen by reflected light they are quite white, but they are most conspicuous by transmitted light, and then, as they are opaque, they appear nearly black. In the leaves they are about the two-thousandth of an inch in diameter, and are of various rounded forms, like long potatoes, or like round potatoes. They consist of a mass of variously-shaped granules, held together by some kind of gum. Sometimes a delicate bit of mycelium may be seen in them, but in general they consist merely of agglutinated granules. In the stalks of the potato they are of much larger size, but are of a looser texture and less definite form. In the tubers again they are of many different sizes. Some of them are rounded and compact, some of them are irregular in shape and very loosely aggregated together, and in some cases little clusters of these opaque granules lie about amongst the starch cells, with little or no mutual cohesion. They are situated in the greatest numbers round the eyes and round the insertion of the stalk on which the tuber is attached, and from which it grows. Now, I make no demand upon your faith in regard to the presence of the sclerotia; they are startlingly visible in the preparations put before you, and have been admitted by all who have seen them. But I must ask you on this occasion to believe that the granular plasmodium from which these bodies are developed, first enters the potato by the young tubers from the mycelium of resting spores in the soil just in the same way as the plasmodium of the club-root fungus enters the turnip bulb. Well, we have thus got potato tubers infested with fungal sclerotia, and looser masses of the same granular particles. These are all visible in the tubers, and must have entered in some way or other. We see them in perfectly fresh tubers, but in such tubers we see nothing of De Bary's hibernating mycelium; nevertheless, these granular bodies are exactly equivalent to such mycelium. But it does not at all follow because these bodies are present in the tubers that they should germinate at any time and produce disease; sclerotia germinate only at certain periods of the year. And so long as these bodies remain quiescent in the potato tubers, they do no harm any more than the crystals found in the tissues of many other plants. Well, the infested tuber is cut into sets and planted. And as the haulm and leaves which result from germination and growth, are mere developments of the tissues of the tuber, the granular fungal matter in the seed tuber is carried up and distributed through the stems and leaves of the plant; and in these accordingly, at all periods of the season, it is found developed into the sclerotia. If those who follow De Bary contend that the hibernating mycelium is carried up with the growing shoots, they can have no difficulty in admitting the translocation of the sclerotic granules. We have only to wait now and see what will become of the little particles lying within the leaves and stalks. A leaf may sometimes be found containing few or no organisms; but in most leaves they exist in great numbers. And certainly it is not to be denied that if they germinate and give rise to the mycelium, which runs through the leaves and produces the oidiotyphora of the peronospora, they are exactly in the position which they should occupy. The upper side of the leaf consists of closely perched palisade cells, while the lower side consists of loose round cells. The sclerotia become developed at the base of the palisade cells. The autumn is now approaching, and you go out some dewy morning, and observe a few black spots on your potato leaves. You take one of these leaves for inspection. You discover very soon that nothing is to be made of the tissue, which is already black; everything is too opaque. But round the black spot you find that there is a peculiar green border, as if that part of the leaf had been squeezed. Teasing out a part of this border, you find that it is permeated in all directions with very irregular lines of mycelium, and that these lines are here and there sending extensions out at the stomata of the lower side of the leaf. You follow these extensions, and you find that they are the stalks which bear the conidia of *peronospora infestans*. This part is easy, and completely satisfactory. But you want to find where the mycelium inside

the leaf takes its rise. Has a zoospore come flying through the air and entered the leaf, or has one or more of the little sclerotia, already inside, simply germinated? I don't wish to make you more certain than I am myself; this question is excessively difficult to answer. The leaf mycelium is of great transparency, and although it gradually attains a considerable diameter and is easily seen, yet at its origin it is of extreme fineness, and unless separated from the tissue of the leaf, cannot be seen at all; while the operation of separating it from the tissue breaks away the threads from their origin, whatever that may be. Nevertheless, in the course of the last three years I have come upon what I regard as sufficient evidence that the mycelium in the leaf and other parts results from the germination of the sclerotia. The granules at the boundaries of these bodies become detached, and throw out lines, which at first are only to be seen with a high power in the most favourable light. Of course you see at once that by this theory every leaf in a field contains the materials producing its own disease. In every infested leaf there are hundreds of more sclerotia that would destroy it. No flying zoospores are here required. The enemy has been lodged inside all the season. And the philosophy of its germination is, that the parasite may be brought to its perfect fruit-bearing condition. In the early period of the disease only one or two spots may arise on a leaf, showing that only one or two centres have germinated; but later on, the sclerotia germinate in all directions over a leaf, and produce little black spots, which gradually run into each other. It is a mistake to say that the disease does not arise till the leaves are turning yellow; the growth of the fungus is most rapid in leaves perfectly green. By this theory you see that no journey of mycelium down the stalks or up the stalks is necessary for the destruction of the stalks. Any one who has closely observed must have seen that a part of a stalk is often diseased while the parts above and below are perfectly fresh and green. This cannot be explained by itinerant mycelium. But it is easily explained on this theory; the sclerotia have germinated where the disease appears, and have not yet germinated above and below. If you make a thin slice of a stalk, and place it during night in moist air, the sclerotia masses will germinate, and in the morning you will have a forest of peronospora, the plants all standing with their fruits on the branches. In the same way with the tubers, a thin slice laid upon a slide will throw up a thicket of conidia-bearers, with the denser growths arising near where the sclerotia are situated. The plums are also liable to be infected with these parasitic granules. They appear first, of course, in the ovary around the seeds and scattered through the walls. So that in autumn you have only to place a few plums in moist air to get a crop of peronospora bursting through the surface, or a thin slice may be placed on a slide, and the fungus will in a few hours be in full fruit. Thus, then, you have a brief outline of the theory or course which the parasite pursues while it is within the tissues of the host plant. The germinal granules are absorbed by the underground stalks, and thus enter the tubers; and on the germination and expansion of the tissues of the tubers, they are carried out with the expanding haulms and foliage. In these they lie, possibly undergoing some secret process of preparation or gestation, till the proper time for germination, when they start into activity, and by the assistance of the juices of the host plant used as food, the purpose of their parasitic life is accomplished in the production of their conidial fruit and seed. But you will naturally ask, what becomes of the fruit and seed? Other theories find a use for the conidia in the spread of the current disease. Here the whole of the current disease has one source, namely, the germination of the granules within the tissues; so that the conidia are no more required for the current crop of peronospora than are the seeds shaken out of a crop of wheat for the current crop of wheat. It would take too much time to go into that part of the life of the fungus which is passed outside of the potato; therefore, I may say, shortly, that when the conidia fall to the ground, they germinate in various ways and give rise to the resting spores or oospores. These grow at any time through the winter, and produce a strong, jointed, brown mycelium. And it is from the granular plasma carried through the soil by this mycelium that the elements of the fungus are again brought into contact with the young tubers of the potato. It is easy to prove that the conidia give rise to the resting spores. If you take half-a-dozen potato leaves on which the disease has begun, and place them against the inside of a bowl, and then invert the bowl on a plate, and pour in a little water to keep the air moist, in the course of six weeks or two months all the conidia will have disappeared, while the leaves which showed no oospores at the beginning will be found swarming with them in great beauty. Thus the life-cycle of the *Peronospora infestans* becomes completed. It could not become completed unless the fungus became a parasite. And I will venture to add that the theory thus imperfectly submitted to you affords a more satisfactory explanation of the phenomenon of the potato disease than any other which has been proposed.

Mr. Wilson, replying to the remarks of several speakers, said: It has been asked why the disease generally first appeared in the leaf. It seemed to be a characteristic of the fungus that it germinated sooner in the leaves owing to their constitution and the constitution of the fungus particles. The theory he had advanced regarding the spread of the disease explained why some of the new varieties of potatoes resisted the disease better than the other theories he had referred to, the explanation being that year after year the potatoes became more charged with the sclerotia. When the tubers got a certain amount of this material into their tissues one year, it was carried on in the young tubers and an addition was made from the soil at the same time, so that by and by, in the course of years, all the potatoes became charged with the germs of the fungus, and would not grow. It appeared that there was something in the constitution of the champion variety of potato which prevented the germination of the disease. Its roots penetrated deeper than some other varieties, and it was a late

potato, and did not come to maturity at the period at which the disease was most liable to appear. It did not ripen until the season had become colder and more unfavourable for the germination of these bodies. That seems to be partly an explanation of the way the champion had more or less resisted the disease.

Mr. Robson asked if Mr. Wilson suggested that by planting diseased tubers they would specially propagate the disease.

Mr. Wilson said the meaning of it was simply that nearly all the tubers at the present day contain matter from which the fungus is produced, so that they found it impossible to plant undiseased potatoes, though the disease was not developed. He did not find that by raising potatoes from seedlings they would escape the disease. Speaking of the Jensen system, he did not believe it was a proof against disease. If they earthed up potatoes and put them further from the light and air, it was perfectly evident that no seed would germinate—it could not germinate except under proper atmospheric conditions. The Jensen system might be a method of diminishing the disease, although his theory might not be correct. The potatoes were put into the soil under new conditions, and the question was, 'Were these new conditions the cause which retarded the germination of the fungus or not?' He thought that might be the real explanation.

WIREWORM AND ITS REMEDIES.

MISS E. ORMEROD, Special Lecturer on Economic Entomology at the College, and Consulting Entomologist to the Royal Agricultural Society, recently delivered a lecture on wireworm to the students of the Royal Agricultural College, Cirencester. The lifetime of the grub, she said, extends over as much as five years, and during this time it feeds in winter as well as in summer, unless the cold is so severe as to cause torpidity, and (with the exception of mustard) it appears to feed on the roots, or underground portion of the leafage, of almost all kinds of common farm crops which may be successively put into the ground. After describing the 'click beetles' which lay the eggs of the wireworm, Miss Ormerod proceeded:—We all know the appearance of the common wireworm by its resemblance to a short piece of flattened wire, or of straw, which it resembles in colour, but some kinds found in decayed leaves or wood are of a deep pitchy brown. All of them have three pairs of little claw legs, and also jaws which they use only too readily. Where wireworm is numerous in wheat or any other growing crop, if this crop is in good heart, or as was often the case last year (1882), if the weather is favourable, we may very possibly escape much damage. Or sometimes we may lessen the amount of injury that is going on by various measures, such as compressing the soil so as to prevent the wireworms travelling through the ground, or using applications which will attract the worm or drive it away, and so give the plant a temporary respite, or which will act as temporary fertilisers. Still, these special measures require special outlay, and it is a much better plan as far as we possibly can to forestall attack; and as wireworm is generally to be found in land broken up from old pastures, clover leys, or sainfoin, the treatment of these, both before and after breaking up, so as to lessen the amount of egg-laying and also to diminish the numbers of the wireworms (which otherwise would have infested each successive crop for years), is an important item in prevention. If we look first at the treatment recommended before breaking up grass or pasture land, or for reducing the ground into proper condition for the succeeding crop, we find the points aimed at are to make the surface quite unattractive for egg-laying, and to starve out the wireworms. For this purpose it is found serviceable to feed sheep or cattle on the ground with cake, or other feeding stuff, 'so that each inch of ground shall be trodden and eaten bare.' In one locality this plan was carried out by penning such sheep as were to be fattened during the winter on the land. The sheep were fed with turnips, oats, and hay. The pen enclosed as much ground as could be thoroughly trodden by the animals in the course of a week, and was then moved forward, going on regularly from one side of the field to the other, the ploughs following regularly so as not to retard spring operations. In this way (or with any adaptation of the principle that may be more convenient) the surface is so completely cleared of grass and herbage, and also sodden and consolidated, or 'firmed,' as it is sometimes phrased, by the droppings and by the trampling of the animals, that the beetle eggs are either not laid on the unsuitable ground, or are for the most part destroyed, and the wireworms are lessened in number, or driven away by want of food and difficulty of travelling in the firm or poisoned ground. Various chemical manures have been found useful for top dressing in the same way. Salt, at the rate of five to six cwt. per acre, has been serviceable in many cases, and applied in heavier dressings up to ten or twelve cwt. some weeks before sowing, it has served not only to diminish the numbers of the wireworm, but also to clear out the twitch or couch grass, which serve for a most favourite headquarters of these insect vermin. Gas lime acts well at the rate of five cwt. the acre, or applied fresh and in larger quantities may be used as a regular killing dressing fairly to stamp out all surface life, insect and vegetable; and 'alkali waste' (where procurable) is a valuable application for the same purpose. In the neighbourhood of chemical works this material is to be had for little if any cost beyond that of carriage, and its strongly caustic properties make it a thoroughly valuable application for killing everything objectionable on which it can be brought to bear. In heavy dressing it destroys the deepest rooted weeds, such as thistles or coltsfoot, as well as couch grass, and in the same way no better in contact with it, and when its first work is over, the process of oxidation turns it to a manure suitable to lead on which gypsum is of use. The general plan followed by many agriculturists may be shortly stated to be this—to have the pastures eaten down as closely as possible, to break up the ground early in autumn, and

to collect and burn all grass, weeds, and roots, which might give shelter or food to eggs or wireworm; to thoroughly cultivate the land by ploughing, grubbing or otherwise, working well in to it lime (especially in a hot state) or lime and salt, or gas lime, or other application unfavourable to insect life. Also such manure and fertilisers should be applied on the land, or drilled with the seed, as will put the crop in good heart. Heavy rolling to compress the soil about the young plants is another important item. Everything alive or dead that can give shelter or food to the wireworm should be destroyed, and collecting and burning it is the most convenient method; but the burning should follow as promptly as possible on the collecting, or else the wireworm which were in the heaps, feeling themselves ill at ease in the unnatural locality, will have gone down into the ground out of reach of injury. The land being kept open by vegetable remains, bears on the question of wireworms being injurious after crops (like beans or field cabbage) of which the oil stalks or some portion of the haulm are ploughed in, and gives an additional reason for prevalence after clover; and it leads further (though it appears very difficult to carry this point out practically) to whether the opinion may be perfectly correct which is held by some of our agriculturists, that the use of farmyard manure, in the state in which it is often worked into the land, encourages wireworm. From the information which we have gained of the common habits of the wireworm, and also of its customs when in emergency there appear to be full reasons for its general prevalence, and amongst these one special point is that the same general conditions which suit the growth of most of our crops suit also this destroyer of them. 'The rainy day is not the time for thatching'; and similarly, when the crop-pests are destroying the plant is *not* the right time for beginning to seek in all directions for how to destroy them—but to do it. In these cases the applications which we usually need are not so much the common plant food as a concentrated essence (so to call it) which we can procure at once, and which, by its rapid solution in rain or moisture, may be available for the plant at once; and also if possible, may at once make the locality so unpleasant to the grub or other insect that the crop may at least have a respite. These effects are more or less brought about by the application of mineral or chemical manures, and as preventives or remedies for wireworm attack there is a long list of them. Lime in its caustic state is always useful as a clearing dressing, and fresh gas lime, or alkali-waste, serves if need be to destroy all insect and weed life where it may be laid. Where alkali-waste is laid on in large amount, it washes down so readily that the drains will run milky at a depth of three feet in heavy land, and it may be to serve as an absolute purifier of all live vermin some way down in the land. We do not often need its application to this extent, but it is very desirable to bear in mind against the sudden appearance of some pest which should be fairly stamped out; and there is a material which for little if any more outlay than the cost of carriage will serve for this purpose, and, after a few months' exposure has neutralised its poisonous properties, will leave all land to which sulphate of lime is applicable all the better for the temporary heavy dressing. Salt given at the rate of 5 to 10 cwt. the acre is serviceable as a dressing before breaking of land, both for killing couch grass and driving out wireworms. Also the property that salt possesses of attracting moisture may be turned to good service on heavy corn land which is infested. The moistened surface becomes rightly incrustated (or firmed, as it is termed), and consequently the wireworms are to some degree prevented from travelling at will amongst the plants. Nitrate of soda pushes on a rapid growth, and is of great value as an antidote to wireworm attack in the straw crops, but little is said regarding the effect of this and salt being used together. Looking at the difficulty of the nitrate being often too stimulating to the growth of the straw and leafage, whilst the effect of the chloride (that is to say, of the common salt) is to prevent undue luxuriance, it would appear worth while to try the effect of the mixture. We thus should have a dressing which, without being too stimulating, would be a thorough fertiliser, and would also cause a condition of surface soil to some extent unsuitable for wireworm movement. Further, judging by the effect of both the nitrate and chloride on other larvae, it might very likely prove so distasteful to the wireworm as at least to diminish the amount of attack. If we know that some common chemical likely to be tried has no effect at all on any given crop pest, this knowledge is valuable as it goes, for it saves the loss of time and capital in trying what its effect may be when the enemy is in the fields. But we greatly need to understand clearly and correctly in what way many dressings and applications which are known to be serviceable as preventive in cases of attack act on the grubs or insects. Most grubs appear rather to die of starvation than to feed on what is not suitable; if we can manage to fairly imbue the soil with anything which in solution must necessarily be in some degree swallowed by the grub as it feeds on the roots in the dressed ground, we must benefit (also in some degree) by the application. We find that in some cases the grub sinks deeper and deeper in the ground to avoid the unwholesome presence, just as it does in the case of increasing frost; but as yet, as far as I am aware, we have no field experiment on these points. Every year the same loss of time and of material goes on in trying; as it is said, and whilst the trial is going forward the crop too often dies. If we had distinct experiments on the direct effects on insect life of soda, kainit, guano—which is said to be not I do not know) to destroy some larvae, and gas lime or alkali-waste, we should then have something to fall back on in the way of information when attack came, which could not fail to be of service. We all know that wireworms are attracted by rape cake, but what is the special method of action of the kind known as Karrachee, or Indian rape, really mustard cake? When in my own experiments I have limited the wireworms to food consisting of little but one of the above two kinds of cake,

I found that although the larvae in the mustard cake feed as greedily as the others for a time, yet in about a fortnight they died; and although when they began to perish I placed other food in their reach, they appeared past recovery and did not touch it. We know that mustard is a good clearing crop, a good means of getting rid of wireworm, and in experiments with the cake I found that wireworm would not enter it until the pungency which follows on mixing this mustard cake with water was gone off, and I would suggest that inquiry into the precise method in which mustard is obnoxious to wireworm would be very useful. If this matter was fully investigated we might find that by a more frequent introduction of mustard into the rotation of crops, we not only cleared the land of wireworm, but on suitable land secured a paying crop of mustard free from the ravages of the mustard beetle, which is too apt to become a ruinous scourge to this crop in districts where its cultivation is widespread and continuous. Time does not allow me now to enter on full details of prevention of the pest we are especially considering; but I wish to draw your attention to its absence sometimes following on the application of seaweed being a matter worth inquiring into, as in this case we have the advantage of a manure often procurable at small cost which contains the alkaline and nitrogenous and mineral constituents we have seen are generally serviceable, joined in some cases to an amount of salt distasteful, to say the least, to the wireworm. We seldom need any teaching as to how a crop insect injures us; that part of its life history is commonly only too plain. But where is it at other times? Where does it pass the winter? How deep does it go down into the ground? What special woods encourage its presence which we, or perhaps our neighbours, are apt to grow in ornamental patches, making, as it is poetically remarked, the country to glow like a garden? But, so surely as you see that golden glow from the charlock blossoms, may you expect a following of turnip fly; so surely as you see the blades of couch grass, or water grass, or any grass or weed in number in your crops, may you be sure there grows a home for wireworms. And so it is with other parts of the attack. Destroy the wireworms (as we have seen can be done) in the land that is infested before you put in your new crop, and it will in great measure escape. Destroy the rubbish in which the turnip beetle shelters in the winter, and destroy the plants where it feeds until we provide more pleasant sustenance at great cost, and we save much of our crop.—*North British Agriculturist.*

THE CULTIVATION OF TEA &c.

A recent meeting of the Maskellia Planter's Association, Mr. T. C. Owen read the following paper upon the cultivation, &c., of tea adopted in Assam and Darjeeling, accompanied with that of Ceylon.

TEA, COFFEE, CINCHONA, CARDAMOM, AND ALONE.

Mr. Chairman and Gentlemen,—The subjects which I propose to bring to your notice to-day deal entirely with those products which are suited for supplementing or replacing the cultivation of coffee, more especially at high and medium elevations. I must premise that I am not one of those who think that remunerative coffee cultivation is altogether a thing of the past, but this subject has been dealt with in such an able way by others, and I so fully concur in all that they have said, that any further remarks on that point are unnecessary.

Of the various produces with which it is proposed to replace coffee, the one which is at present attracting the greatest attention is undoubtedly tea. Eight years' experience of its planting and cultivation in Ceylon, with the results of an extended trip through the Assam, Darjeeling, and Terai districts, which I was able to make recently, have enabled me to form some conclusions on the subject which may be of interest to others.

The general conditions under which cultivation is carried on in Assam are utterly different from those which characterize the hills in Ceylon; the nearest approach to our circumstances being found in the Darjeeling hill district, which therefore possesses a special interest for us. The land there is very steep, as steep as anything that is generally planted with coffee, but it is worked in a different way. In Assam and the Terai the land is perfectly flat, that which is suitable for tea consisting of raised banks of dry soil surrounded by swampy land unfit for cultivation. The soil in Darjeeling is very variable. The upper portions of the hills are yellow clay with very little surface soil, but the clay seems to be especially rich, for the tea flourishes in it wonderfully. Lower down towards the ravines and rivers, the character of the soil entirely changes, and it becomes a rich black micaceous loam of great depth. In the Terai, the surface soil is very rich and fertile, but underlying it at no great depth is a barren gravelly subsoil; the result is that when young the tea flourishes luxuriantly, but when old the results become disappointing. Assam has a very rich loamy soil in most places, which is exceedingly deep, 20 feet and more sometimes, and of a remarkably fertile character. It is evident that the success of tea depends on the depth and quality of the subsoil more than anything else. The Darjeeling clay is very similar to what we are so familiar with in Ceylon, and the fact that tea sends its roots down into it freely, and grows healthily, should make us confident as to its future in our stiff lands.

Now, this subject of soil is a very important one for us; its importance cannot, in fact, be over-rated, and the chief question we have to decide is this:—Is the Darjeeling hill-soil of such a nature as to lead us to hope that our Ceylon tea will be a *permanency*? That our young tea will bear, and bear well, has been conclusively proved, as I shall show later: will this last? As I have said, the Darjeeling soil is very variable; some are apparently very inferior to much of ours (I speak as a practical planter, not as an agricultural

chetist); some, superior to anything we have. As an illustration, I will take go the Singtoen estate. The upper portions of this garden are stiff and clayey that a walk of half-a-mile down-hill, without a fall is a real feat. As we go lower the clay becomes covered to a greater depth with a rich black micaceous loam. This garden is a very old one, and without manure of any kind the tea is yielding a better crop this year than it has done for a long time. The estimated yield is about 320 lb. an acre, a large yield for the locality as I shall show later. The manager tells me that the lower portions bear better than the upper; but the latter, in spite of having an inferior *jat* of tea in them, and in spite of a less favourable climate, bear well and pay handsomely. I have also seen land very much of the same character as some of ours up country, a light loam, growing good and permanent tea in the same locality, and I unhesitatingly say that if you have depth you need have no fear of its future. The Terai is a most important instance of the uselessness of rich soil if an unfertile sub-stratum underlies it. We have not, as a rule, rich soil in these districts, we have nothing as good as the soil of the best localities in Assam, but we have better soil than some districts even in that favoured province (and as an instance I will name Gowhatti), and we have plenty of it. Those that have a good depth of such soil as I have described on their estates, although it is not apparently very rich and even though it is clayey, may plant tea without fear for the future; but I would warn you against shallow soils over-lying gravel or rock as sure to lead to disappointment.

In all the Indian tea districts there are great changes of climate during the year, to which we have no parallel down south. In October the approach of the cold weather begins to be felt, and in November and December there is a veritable winter characterized by snow on the upper Darjeeling gardens, which causes a universal stoppage of all growth. In March and April there is a commencement of growth again but this is not fully started till May. The consequence of this is that whereas in Ceylon we have growing and consequently plucking weather all the year round, in India they have only five really good crop-months. During these months their growth of leaf, and of weeds too, is of course far more luxuriant than ours. The unhealthiness of the Terai and Assam climate in the rains is proverbial, and I will not enlarge on it but merely point out that with expensive imported labour an epidemic means ruinous loss in every way, that with local labour it means wholesale desertion, and that it also means high and costly remuneration to Europeans and other employees.

In the matter of *jat* we are behind India. The fatal error of planting China and low-class hybrid was originally made in all the Indian districts; but now public opinion has run in the other extreme, and in the plains none but indigenous seed, at Rs. 150 per pound, is bought, and on the hills a good high-class hardy hybrid is gone in for. And here I would warn every one against being induced to plant China or low-class tea at any elevation in Ceylon. Hybrid of the right kind will grow well, and inferior *jat* means a decreased yield and a comparatively weak tea. On Ononagalla this year I manufactured the two separately, and sent them to the London market; at a recent sale the hybrid tea was well reported on and averaged 1s 4½d all round, whilst the China averaged 1s. 2½d. and was spoken of as a poor tea. Very fine tea is made from China plant in Darjeeling no doubt, but that from hybrid bushes is in every case finer when the two are grown together.

And not only this, amongst hybrid plants, the nearer the *jat* approaches the indigenous type, the stronger and more telling is the liquor and the better the tea. I have proved by experience that this rule holds good for both Ceylon and India. Plant, therefore, the best class of hybrid you can get hold of in these districts, even though it entails an extra cost, which, after all, spread over your acreage, amounts to a very trifling additional expense in opening, and you will never regret it. Coming fresh as I do from a country where I have seen old low-class tea being rooted out to give place to a better kind, I emphasize this statement.

As regards labour facilities, Ceylon has a decided advantage. The rate of pay in India is considerably less, Rs. 3 to Rs 6 a month for women and men; but then in Assam every imported labourer costs upwards of Rs. 100 for a three-years' agreement, at the end of which a bonus has to be given for its renewal, whilst there are numerous costly and vexatious Government restrictions. (Refer to copy of forms). In Darjeeling and the Terai, all the work is done by local labour which is very cheap, but here it is necessary in many cases to give over large areas of valuable land to the coolies for Indian corn cultivation (in one place I saw as much as 100 acres or more so treated); and this item, one which does not appear in any accounts, is a matter of some moment.

In transport, the many advantages possessed by Ceylon over Assam are evident; but Darjeeling in this respect, as in the matter of labour, is more on terms of equality with us. At present, the only means of communication with Assam is by a steamer-service on the Brahmapootra, which charges the most exorbitant rates for freight up, and which is scarcely more equitable in its charges for tea down, to Calcutta. About three cents per lb. seems to be the lowest average cost for tea down from Upper Assam to Calcutta, and this would be higher when much land-transport is necessary. The freight upon tea lead, nails and all factory requirements is however the most serious item, and the one which makes all these necessities so expensive when landed on the gardens. Darjeeling, with its railway up into the district, is much better off in this respect, and were it not for its small yield would be a dangerous rival to Ceylon. The Dooars, a district situated at the foot of the hills, similar to the Terai but to the east of it, possesses almost the same advantages of transport and labour as Darjeeling, and is better circumstanced in the matter of soil than the Terai. This is undoubtedly the rising district of India, and the one which will run us the closest in the future.

The Indian methods of planting and cultivation are very different from ours. Nurseries cover a much larger extent of ground, the

seed being generally put in five inches apart to allow of ball planting which is universally practised. It was the general opinion that plants put out in the Ceylon way, without any earth about the roots which are sometimes lightly pruned, would not stand a chance owing to the excessive power of the sun when it does show during the rains. The general planting distance for hybrid bushes is 4 by 4, indigenous plants in the best land in Assam being put 5 by 5 and sometimes even 6 by 6. The first distance mentioned is by far the most general, and the one suitable for adoption in Ceylon, though very poor land of course might be planted closer.

As regards planting, Mr. Armstrong has anticipated all that I had purposed saying on the subject. I have found by experience that attempts to suit lining-distances to that of the coffee is a great mistake. It is far better to line the field *de novo*, without any regard to the coffee trees, the lining rope being stretched along the ground. As to holling, I would always make the holes 15 in. deep, and have found that a deep hole does best, breadth 1½ of little consequence; nine inches, about sufficient for the coolie to work in, is enough. A good lining-distance through coffee is 3½ ft. up the lines and 4 ft. between them, and this latter distance should not be decreased except in very poor land.

Various schemes have been suggested as to the best way of combining coffee and tea cultivation until the latter begins to yield. Now I would strongly dissuade any one from attempting to raise certain lines of tea before others as sure to lead to trouble. For instance, some people plant lines of tea up between the rows with a plant between each pair of coffee trees up them, intending in two years' time to uproot the coffee, and put a tea plant in instead. This or any similar method will infallibly give great trouble, and probably result in a patchy garden. When supplies abound, the difficulty and trouble of keeping pruners and pluckers from touching them is inconceivable to those who have not experienced it.

Steep land in India is very commonly terraced. The laws of plants are made across the face of the hill and not up and down it, and the terraces are formed by a succession of hoeings along the lines. On stiff land terracing is dispensed with, and though no drains are cut there is remarkably little wash. The ground is always kept covered with a thick growth of weeds, which in the flats are kept down by constant hoeings, on the hills by sloking. The land is so thoroughly impregnated with weed seed and the growth of all vegetation is so rapid during the rains, that clean weeding is an impossibility, and those methods of cultivation are the only ones possible. Draining, too, is impracticable in many places when there is not a stiff sub-soil to cut into. The result of observation is to convince me that, whilst our present system of cultivation is the right and proper one, and incapable of improvement as far as India is concerned, that adopted there is the only practicable one under their circumstances. Their system is of course a much more expensive one than ours, and, in spite of the fact that no cultivation whatever is required during the cold weather, the rains being the only time when hoeing is necessary, its cost is upwards of three times as much as that of clean weeding from the first. The growth of plants under the most favourable circumstances in Assam is about on a par with that in the Ceylon low-country, but under ordinary conditions I think it is hardly as satisfactory. This method of comparison is, however, a very unsatisfactory one, and in view of the facts and figures now at our command, it is unnecessary. Suffice it that, broadly speaking, a two-year-old-plant will be much the same size on a good Assam garden as on a Ceylon low-country plantation, whilst on the hills it is impossible to make any comparison between India and Ceylon, the advantage in favour of the latter being so astonishingly great.

The great point is, of course, yield. How does the Indian yield compare with that of Ceylon gardens? Amongst the numerous Assam gardens I visited, the best in every way, cultivation, *jat* and soil, was the Borell Company's, and it is known as one of the best in Assam. The yield last year was 7½ maunds or 580 lb. per acre. This and a few other gardens of specially fine character apart, 3, 4 and 5 maunds per acre represent the yield of the bulk of the good Assam plantations, say from 240 to 400 lb. (p. 297, I. T. G.) From my experience of the Ceylon low-country, I feel convinced that a yield, as high if not higher than the exceptional one previously mentioned, will be very generally got on good gardens, the average being much higher than that of Assam. But our more immediate subject is a comparison of hill-tea in the two countries, and on this point there can by no possibility be a difference of opinion. The ordinary yield in Darjeeling is between 2 and 4 maunds per acre, the latter amount being considered remarkably good. There can be no question, from the results already obtained, that this will be very considerably exceeded in Ceylon, and we are all aware of numerous instances to show this. I need here merely refer you to the figures brought forward by Mr. Armstrong in support of this statement, which show conclusively that his estimate of 400 lb. per acre for hill gardens is by no means an over-sanguine one. I think this estimate of yield, judging from your soil and climate and in respect of the results actually obtained elsewhere, is a very reasonable one, and not likely to prove misleading. Actual figures and results apart, a visit to the Indian tea gardens is quite sufficient to show plainly their inferiority to ours; the period of growth during the year is very short, and at a high elevation insufficient to force out any considerable quantity of leaf.

Regarding quality of tea, there is little to be said in view of the very fine prices now being obtained by all properly managed estates. To any one comparing Ceylon hill and low country teas with those from the Indian districts, it is evident that ours possess a character of their own, and that they are not altogether comparable to Indian. Our low-country teas have not the rasping pungency of Assams, and this difference is more marked in the coarser qualities than in the finer. Our hill-teas also have none of them the Darjeeling flavor, but are characterized by a distinct hill flavor peculiar to them. It

is a peculiarity of Ceylon teas that those grown in the low-country possess a flavor combined with their strength which Assam's lack. There is one fact very generally lost sight of in comparing the prices of Indian and Ceylon teas, and that is, that most of the best marks are sold locally in Calcutta, and do not of necessity appear at public auction in the London market at all. Though, therefore, the position already taken by Ceylon tea must be a source of satisfaction to all interested, we must not suppose that we have attained perfection by any means, nor must we imagine that India is already behind us in the race for quality (*J. T. G.*, p. 308.) That there is in reality not much we have to learn is the conclusion forced on me by visits to numerous factories, in various localities, but yet there is something; and there were few gardens where something to improve or something to avoid was not noticeable. And here I must put on record and mention the excessive kindness and hospitality which is to be met with everywhere in India; not one single garden did I visit where everything was not thrown open to my inspection, and where every information was not given.

I will now say a few words on manufacture, as far as Mr. Armstrong's paper leaves me the opportunity. The system of manufacture as described by him and practised by us agrees very closely with that in India. Withering trays for withering are not generally in use. In Assam large temporary iron-roofed sheds are erected, consisting of 2 or 3 stories, and in them the leaf is thrown. In Darjeeling more permanent buildings are erected, and the leaf spread on flat round bamboo baskets, which are roughly made and ranged in tiers on racks to support them. I think our system is preferable, as being an economy of space, but I would advise that a portion of the withering-house be left free, and that here a number of loose bamboo trays be stocked, in which sun-withering when necessary can be arranged. In our damp climate it is frequently happens that by the morning the leaf is still unwithered, and half-an-hour's exposure to sun or light will finish it off and save time. Hand-rolling is unknown in India, as far as my experience goes, and even for the second rolling after fermentation a machine is employed. Regarding so-called fermentation—for I believe this to be a misnomer and that oxidation would be a more correct term—it is a good plan to mix the roll several times during the process, as this makes the colour much more even. In fact, in a hot climate, I would employ boys in turning the roll over constantly, and I have seen some of the best manufactured teas in Assam and the Teas made this way. It is not a bad plan, after machine-rolling, to sift the roll through a No. 4 sieve and ferment the small and big leaf separately; this will enable you to colour your coarse souchong leaf without overdoing the pekoe and broken. Where roll is constantly turned however (and it is quite practicable where colour is obtained in an hour or so) this sifting is unnecessary, an even colour being obtained without it.

As to firing, a machine-dryer, being generally purchased after the roller, the method of performing this work by hand is of some importance. The stoves recommended by Mr. Armstrong are better than the long open troughs sometimes used. But the system of firing in India is better than that that recommended by him. The shape and dimensions of the stove are similar, but the opening at the bottom is bigger, about 15-in. square. The air-hole, not alluded to by him, is a most important point, and on its size the efficient consumption of the charcoal depends. It should be about 9-in. high and 6-in. broad, and no grate whatever should be used. The whole bottom of the stove should be filled with charcoal and kindled until the mass is in a glow; then—and here comes the secret—the fire is masked by a thick layer of ashes, a stock of which is always kept on hand. In using a grate, the charcoal has to be lighted outside and brought to the stove glowing, to prevent the possibility of smoke from ill-burnt fuel, and a great loss of heat is entailed by this. 1 lb. of charcoal does 1 lb. tea by the Indian method, as against a bushel of charcoal to from 8 to 10 lb. by the latter system. Again, 24 and 26 mesh-firing sieves as recommended by Mr. Armstrong have been given up in favour of 12 to 16 meshes. The larger meshes allow the tea to fire quicker, and very commonly the broken pekoe is sieved out through them permanently, thus saving subsequent labour and the use of sieves during firing, at all times a troublesome method. I was told also, but cannot vouch for the fact, that burning was less common with a large than with a small mesh sieve, scorching being due to the wire getting too hot in the case of the latter. One map to six trays is the usual allowance, and each firer's tea is kept separate till the next day and weighed and even tasted separately some time. An Indian tea-house assistant can always point out his best firer.

Sorting is very commonly done by hand. With a China sieve (made of fine bamboo), I have seen a good man sift a whole bulk of tea through with a No. 10 only, all done by altering the angle of inclination of the sieve. In fact, much depends on the degree to which sieving is done, and work done with the same sieve by different coolies is not always similar. Much variety can be introduced into this work; but the great principle is to sift into as few qualities as possible.

Regarding Packing.—In chests, split cases are an admirable substitute for hoop-iron, or small clips which just embrace the corners. With this substitute for hoop-iron, I certainly think factories near a cart-road ought to use chests, and so effect the saving in lead, cost of packing and draft which this means. As to wood for tea boxes, in India, Burmah teak is generally used, and out of all the numerous species growing locally, none is yet in common use. In Ceylon, I have always used Mallebodie, that despised tree which every one gets rid of. If seasoned properly and used soon, it is perfect in every way, being light, free from smell, and holding a nail well. It must not be kept too long, however, or insects will attack it.

The arrangement of the factory may well be left to the ingenuity of the manager, as it is generally a converted coffee estate. The great points to be borne in mind are, that the withering-room should be immediately under the roof, and above all heat-creating

machinery and stoves; that the engine-room or water wheel should be out off as much as possible from the rest of building, also that ample light should be provided for everywhere.

In tasting, all defects in manufacture become apparent, and by means of samples the work being done in any factory can be checked. I have here the Awisawella estate samples which gained the silver medal in Colombo, and of which the bulk averaged is, 741, at the last sales, the broken pekoe fetching 2s. 7½d.; this was made under the same immediate supervision of a gentleman who knew nothing of tea manufacture nine months ago.

In regard to machinery, I have a few words to say. In a small garden that will not give bigger accumulations than 1,000 lb. leaf per diem to be worked off, a "Universal" roller and a "Sirocco" are most suitable machines. It is, however, an axiom in India that rolling and firing power must always be provided for about double the quantity of leaf that has to be expected under ordinary circumstances, and I think there are few Ceylon estates where the machines in question would be found sufficient during a rush of crop or a continuance of unfavourable weather. Assuming therefore, that quantities of leaf up to 2,000 lb. will have to be dealt with, an "Exochlor" roller is the best machine to erect, but I do not agree that a multiplication of "Siroccos" is either economical or advisable as suggested by Mr. Armstrong. Kinmond's No. 2 Dryer costs £220 and does the work of exactly four Siroccos costing in the aggregate £340, the cost of erection of one machine as against four would make the divergence still greater. Teas from Siroccos are characterized by a very brisk full liquor, undoubtedly superior to those fired over charcoal; but having had opportunities of sampling them against teas from Kinmond's machine, I am strongly of opinion that the latter carries off the palm. A Kinmond's machine requires five coolies to work it; four Siroccos would require twelve coolies to keep them going. So that, in original cost, working expenses and efficiency of work, the policy of erecting one good machine is preferable to that of maintaining several inefficient ones, however satisfactory the quality of their work.

And now as to the machinery; for gardens working off upwards of 10,000 lb. leaf per diem: two "Exochlors" may be erected, or one "Haworth's" roller. This latter machine is very popular in Assam, and will roll 1,100 lb. leaf an hour. I believe the cost is about the same as an "Exochlor," but am not quite sure. The machine consists of three parallel rollers revolving very rapidly in the same direction. Between them the leaf, enclosed in a bag, is placed. This machine does excellent work. Of dryers to work on a large scale, there is none to equal Gibb's and Barry's. This machine consists of a long iron cylinder, made to revolve in its axis, and with a slight slope towards one end. Hot air is driven into it by fans along a shaft which traverses it from end to end. The roll is put in at the upper end, and comes out at the bottom & fired. The temperature of the hot air is from 650° to 700°, as against 750° for the Sirocco. To finish the tea off, it is put through again from time to time as the fired tea accumulates, as a reduced temperature. Those who have sampled teas from these machines would be able to recognize the high-fired flavor and the peculiar twist of the tea any where, and they like it better than teas from any other machine yet invented. The higher the temperature at which tea is fired the better the liquor, provided always that there is no burning; and under-firing arising from over-caution in manufacture is a very common fault with us. The cost of this dryer would be about Rs. 4,000 erected, and it requires about ½ H.P. to drive the fan, as does Kinmond's, but it is unquestionably the machine of the future. I would add that for this enormous quantity of tea, three coolies only are required.

As to sifters, I believe an efficient apparatus as any one requires can be made and erected on the estate, without large outlays in patent machines, and I saw many of the former in India. The most favourite patent machine is Ansell's, and the saving it effects in the cost of sieving is very great: in the Borelli garden one such machine saved Rs. 750 expenditure during last year alone. It does not, however, do very effectual work, as the pekoe is not properly taken out; and I have seen tea put through it three times before it could be said to be thoroughly done.

To describe the numerous other forms of machinery and small appliances would take up too much time, but I hope to publish my notes on them shortly.

To sum up this subject, machinery as applied to tea manufacture is universal in Assam, and, in forming our estimates in Ceylon, we might as well draw up the figures for coffee without palpers, on the supposition that coolies would tread out the cherry with their feet, as against the advantages in every respect, including cost, efficiency, saving of labour for other works, economy of space, &c., &c., when compiling figures in connection with tea. Comparisons of cost with India, where machinery is almost universally employed, are misleading unless we credit Ceylon with the same advantages.

And now regarding the cost of putting teas in the London market. What has gone before will have shown that, in respect of labour, transport and field cultivation, we have a great advantage over Assam, a slight one only over Darjeeling. There is yet another advantage in our favour. During the protracted cold weather in India, there is great difficulty in finding employment for the coolies. All crop work is at an end, hoeing is impossible, and the only work there is pruning. If, therefore, there is no new extension in which to employ the labour, much of it has to be put to unremunerative works. In Assam with imported labour, the difficulty is especially great. The Government insist on the payment of coolies whether employed or not, whether sick or well; the four-days-a-week system is impossible. Now, in Ceylon, with our continuous growth which allows us to choose our own time for pruning, masters can be so arranged that no protracted slack season occurs, plucking in the first pruned portions commencing before pruning is ended. What a great advantage this is will be appre-

olated by all who have in years gone by had to support large crop labour-forces with no work to give them. With the disadvantages enumerated, the cost of Assam tea delivered in London ranges generally between 10s. and 1s., though often over the latter amount. Taking the lower rate at which the Borelli garden is quoted, and deduct 2s. for freight and London charges, we have a cost of 7s. 10. b. in Calcutta. The average cost of the whole of the Land Mortgage Bank's Darjeeling gardens is 6s. per lb. in Calcutta, showing the advantage the latter district has as regards economy of working, for, in spite of a very much smaller yield, the cost of production is less by 1d. per lb. Now with proper appliances in the way of machinery, and with the various economies in the matter of working which come with experience, there is little doubt that gardens favourably circumstanced can put teas in Colombo for 80 cents or 6s. sterling per lb., a yield of 400 to 450 per acre being given. In this case we have an advantage of 1d. per lb. over Darjeeling, due to our superior yield, and of 1 1/2d. per lb. over one of the exceptionally good estates in Assam, the majority being at far greater disadvantages. It will perhaps be thought that 30 cents per lb. is a low estimate, but judging from the cost of the various field works and of manufacture in the large Indian factories, I feel convinced that we shall be able to work for this when our estates are in full bearing, and when we have provided ourselves with roomy factories and the proper labour-saving appliances. At present, with only a rolling machine and with much young tea, 36 cents per lb. is what its production is costing me, and it is easy to see how the 6 cents can be saved in the future.

It had been my intention at this point to enter into details regarding the cost of production, and to show how the figures quoted above were arrived at; but in view of Mr. Armstrong's recent paper on the subject, and of the very close approximation between my figures and his, I will not do so. Mr. Armstrong gives the cost of production by hand-rolling as 39 cents per lb., with machinery 31 1/2 cents: both these estimates include the manuring of 50 acres and a yield of 400 lb. A slightly increased yield, or superior situation as regards transport, water-power, or timber supply would at once bring the cost to the figure I have quoted, 30 cents, or even below it. In practice, the cost will be found to lie between these figures 30 and 32 cents, according to circumstances, with an additional 7 cents where machinery has not been erected.

The average of the four estates enumerated by Mr. Armstrong is 34 cents f.o.b. without machinery. With the proper appliances the cost would therefore be well below the figure I have indicated, but probably the estates in question have done no manuring, which, if done on the scale indicated, would about cover the difference.

And now I am going to say a few words on the subject of pruning and plucking. The object of pruning is to secure as large a surface as possible for subsequent plucking, and it therefore follows from the growth of a hybrid bush, which generally has a clean stem for some inches above ground, and, above that, lateral branches growing in an up right direction, the higher the level at which the bush is cut, the greater the surface will be. Again, whilst all trailing side-branches should of course be cut off, it is evident that any shortening of healthy laterals is a curtailment of the size of the bush, that is, of its plucking surface. For some years in Ceylon we were in the habit of cutting our hybrid bush at 2' 6" and over, never under (exceptional circumstances apart), we are thus enabled to get a large plucking surface at this height, and this system, graphically described by Mr. Armstrong, is the one I most strongly advocate, and have always practised. When the late Mr. Cameron took up his work here, he changed this method in all the estates under his management, and introduced a severe cutting down system. Now the effect of cutting down young bushes, and at present I am confining my remarks to these, is to immediately induce a bush of wood supported by all the youthful vigour of the tree; if this is allowed to grow up, a new tree will be formed, and will be supported by the mass of foliage on the new growth. If however this is plucked and kept at a low level, sufficient foliage is not maintained to nourish the tree and promote a healthy growth of root and stem. The only circumstances under which low pruning—stick pruning as it is called, is resorted to, is to remedy the effects of injudicious plucking and pruning on old worn-out bushes. In one case only did I see this plan resorted to in India. An old piece of tea, the upper branches of which had got gnarled and hard, was cut down to within one foot of the ground; the growth which succeeded was however allowed to attain a height of 2 feet, to mature in fact, before it was touched. This remedy would of course never have been necessary; the trees could never have got into this condition had a proper system of selecting wood and cutting out all that had got hard and unprofitable, been followed out at the yearly pruning. With young tea, however, the great point is easy treatment, if a permanently profitable bush is required; and in succeeding years, with proper scientific pruning, cutting down should never be necessary. Mr. Armstrong has laid down a few concise rules on the subject, which all should study carefully and follow consistently, and I will not attempt to confuse matters by giving a repetition of his advice in other words. China tea has, of course, to be pruned in a very different way to Assam hybrid, the former is a bush, the latter a tree, and as such they have to be treated.

The style of plucking depends greatly on the pruning which has preceded it, on the type of plant, on the climate, and so on. In this work again, Mr. Cameron introduced a new system, very different to that which we had always followed previously. It is generally considered that the point of his system was the plucking of the whole estate in eight days, but this is scarcely correct. The perfection of work theoretically would be to round off the estate at even shorter intervals; the point is, what is the description of shoot allowed to be plucked at each round? We might go round the estate every week taking shoots with five leaves and not less, or we might, at similar intervals, take a leaf and a bud as our minimum, and both would be weekly pluckings. In India the

system of severe pruning and close plucking in question has been tried, and was discarded years ago as being fatal to the well-being of the tree. The matter was made a subject of discussion by me with several of the leading Indian planters, and in every case the system was condemned in the most unqualified way as being a very destructive one giving due strong teas and a good immediate yield, but as being absolutely fatal to the future of the plant. Now, the fact of the system having been such a fatal one in India has been stated by many—and I believe Mr. Cameron did not deny this himself—but it is maintained that in Ceylon circumstances are different, and that the system, though a failure there, will succeed here. I uphold that in Ceylon an earlier style of working the tree, one which draws less upon its energies, is essential for its well-being, and for this there are good and sound reasons. With a very vigorous growth, concentrated so to speak into a few months, such as they have in India, severe plucking will, it is reasonable to suppose, be answered by determined efforts on the part of the tree to form wood; this is the case, but the result of the treatment is that the tree wears it itself out in a few years, stinks, and has to be allowed a rest before it can be made to yield again, whilst liberal applications of manure are required (in one case, and I here allude to the Chittagong estate which Mr. Cameron was in charge of, of 4 years' rest was necessary after two or three years of this treatment. If this is the case in India, is it not reasonable to suppose that the same system, extended over the long flushing period of Ceylon bushes, with the less vigorous growth which accompanies them, should have an even more fatal effect? I cannot think there can be two opinions on the point, and from what I have seen of the results of the system in the low country and in the hills too, I feel convinced that disappointment is in store in the future for those who continue to take too much out of their bushes by hard plucking following the severe pruning. I have seen stretches of tea in the Ceylon low-country, after a few weeks' dry weather, looking as if a fire had run over them where Mr. Cameron's system of plucking has been strictly adhered to. It is obvious that unless sufficient leaf surface is left on each shoot, the circulation of sap cannot be maintained, and hence on the occurrence of the first trying weather, the whole shoot, on which depends the crop, and on the vigour of which depends the quality of our pruning wood for the succeeding year, is irremediably ruined. Just as we must treat our young trees easily, by topping them at first at 3ft. to 3ft. 6in., with a view of preserving the foliage on which their vigour depends and until the last few pluckings when less care is required, systematically leaves a sufficiency of leaf-surface on the shoots that are yielding us our flushes. In plucking, as in pruning, Mr. Armstrong and I are advocating no new system: we are simply maintaining the one which we, with Mr. Taylor and others, have always consistently followed, and on which have attended results which, as a permanency, will be yielded by no other in India or Ceylon.

There is another point in which some difference of opinion appears to exist. I refer to the plucking of the sides of the bushes. In view of the principle previously enunciated, that yield depends on plucking surface, it is evident that this practice is a bad one, and injurious to the growth of young trees. Under certain circumstances, it may be indulged in, but I have seen it practised and advocated in Ceylon where its effects could not but be injurious in the extreme. There are places where young tea so treated is seen dotted at intervals over the ground, instead of covering the hill-side with trees, visible as such even after pruning, and I have even seen an endeavour made to cure the defective yield by supplying what ought to be a sufficiently closely planted field. The effects of this treatment, justly deemed murderous by Mr. Armstrong, are so obvious that it is strange they are not apparent to every one. Coming from Indian tea, they strike me forcibly.

In respect of manuring there is nothing of importance to be learnt in India, and we shall have to gain our own experience. In some cases no doubt manure is applied, but these seem very exceptional. There is one more important point to be mentioned, the extension of tea cultivation in India as affecting our future prospects. An influential firm in Calcutta is now engaged in the most extensive opening operations in Cachar and the Dooars. I forget at the moment how many thousand acres are to be put into tea within a few years, but the extent is considerable. In Lower Assam and in Darjeeling, it is difficult if not impossible to get land, all that is available having been taken up long ago; but in other districts the openings are very extensive. I do not think however we need be afraid of this competition. At present prices, it is only by severe economy that good dividends are paid by Indian Companies, whilst we can well afford to produce tea and gain a fair profit, even should a fall of 2d. per lb. on the present market rate have to be faced.

In this case, I do not wish to make a statement without ample proof in the form of facts and figures to support it. Mr. Armstrong has here again forestalled me by showing that at his figures a net price of s. in Colombo, or say 60 cents, is equivalent to a profit of Rs. 120 per acre, or, without manure expenditure, Rs. 132 per acre. Now, our present sale prices are showing averages of from 1s. 8d. to 1s. 8d. and over, well made teas rarely averaging under 1s. 4d. A fall of 2d. per lb. therefore would still leave a margin of profit which should be sufficient for any proprietor. Now let us see how such a fall would affect Indian Companies. The Borelli Company gave 8 per cent last year with a profit of 3s. 4d. per lb.; Jorahant 8 per cent at 1s. 4d. per lb.; Doon-Doon, 5 per cent at 1s. 4d. per lb. The Darjeeling Companies at an average price of 1s. 3d. gave 6 per cent, whilst the average price of 15 million lbs., tea as given by Messrs. Thompson & Co., is 1s. 1 1/2d. I will not multiply instances, those I have fixed upon including some of the most flourishing concerns, and what the effect of a considerable fall of price in their dividends would be is evident. "Low prices" is even now the burden of most reports. I have here the reports and statistics

from which these figures are taken, and shall be happy to show them to any one who cares to examine them.

Finally, I must add my testimony to that of others, and state that I consider these districts, judging from my Ceylon and Indian experience, to be well adapted to the cultivation.

The lay of land is perfect for a hill district. The soil is in spots poor, and not likely to grow good tea, but the large bulk of what I have seen has depth and is eminently suitable, whilst the lower portions of the district, judging from what I am told of their general character, could scarcely be better. That there can be no fear as regards elevation Mr. Armstrong's figures have conclusively shown, and the elevation of much of the Darjeeling tea adds weight to the testimony. The white clay which is found in the flats in some localities should not, in my opinion, be planted, the free soil of the hill-sides being much more suitable.

I should like to say more on this subject and many others in connection with tea, but time will not permit, and I must pass on to other matters.

CARDAMOMS.

I will now make a few remarks on the subject of cardamom cultivation. This product, when planted in proper situations is about the most profitable that we have in Ceylon at present; in unsuitable sites, however, it is usually an unmitigated failure. Shelter is essential to it, and it grows best in hollows, protected from the monsoon winds, and where there is generally an accumulation of rich soil. It does not bear well in poor gravelly soil, but prefers a rich loam. An important point regarding it is the question of shade. This should not be too thick, so as to exclude light and air, but should be partial only, and in such places cardamoms thrive best. Whether or not any extent of it can be planted in the open is as yet an undecided question with many. My personal experience is against it, as I have found that the growth of the plant is slow and the racemes very short when much exposed. In some cases individual plants in the open are found bearing fairly well; in other cases they do not bear at all in such situations, but it would seem as if a partial exposure only to the sun is not much against them. As to their cultivation amongst the coffee, there can be little doubt that it would be a success where the latter is thick, affording effectual shelter to the young plants but in such situations the coffee as a rule repays cultivation, and does not require to be superseded by anything else. In a few words plant cardamoms under forest-shade on any suitable land, but regard its cultivation in the open and amongst coffee as an experiment only. There need be no fear as to its bearing powers at this elevation, as I have cardamoms bearing freely above the elevation at which coffee ceases to crop. I would also mention that in the low country, at a few hundred feet only, they are bearing well. In a recent letter to the *Observer*, on the subject of cardamoms, published during my absence from the island, and couched in somewhat vague and incoherent phraseology, the writer states that the villagers have not the best variety of cardamoms, and that the somewhat obscure but ever valuable so called "Mysore" species should be rooted out. I merely allude to the matter to re-assure those who may have been misled by this rash statement, for, in the Kotmale, Peradeniya and Kandy villages, Malabar cardamoms are freely cultivated and those who know how to distinguish them run no risk in purchasing bulbs from these sources, whilst in high elevations the Mysore bears much more freely than the Malabar species. In good soil, cardamoms should not be planted too close, 7 by 7 in most cases, and 8 by 8 when the soil is exceptionally rich will be found right. Holes 18 in. wide and 1 yd deep should be cut, and the plant put in shallow, the earth not above the collar. This latter point is very important, as deep planting is fatal. In purchasing bulbs, the closest supervision should be exercised, and all that are out about and injured (and the Singhalese are very careless in this matter) should be unhesitatingly rejected, double bulbs also should always be insisted on, and two single ones instead, such as the contractor will sometimes offer, be refused. The plants will begin to throw out racemes in 18 months at low elevation, but in these districts it will probably be 2½ or 3 years before they begin to do so.

The cultivation of cardamoms is a very simple and cheap matter the stools must be kept clean and free from debris of all kinds, especially when the plant begins to throw out racemes. Weeding after the ground is covered will be found unnecessary, for nothing grows under their shade; it is, however, desirable to send a few coolies occasionally to clear up open spots and corners which some times get dirty.

In order to make the most of the crop to get the highest value possible for the yield of the small acreages we generally possess, the somewhat expensive method of cutting off the capsules with scissors must be undertaken, and they must be picked when first turning colour, before they are fully ripe. Ripe fruit invariably splits, as also a very large proportion of what is taken off without its stalk. The difference of value between split cardamoms and those which are alone fit for the home market is very great, as much as Rs. 1 for the former and 9s. for the latter in some cases. As regards yield, I have got crops varying from 120 to 300 lbs per acre. The cost of putting cardamoms in Colombo is 40 cents per lb., the average price from 5s. to 6s., a calculation of Rs. 2 per lb. net is, therefore, very safe. The profit which these figures leave is an ample one, and is shown in the appended estimate drawn from actual results. Mr. Owen here introduced and explained the estimate appended to his manual.]

CINCHONA.

I will now say a few words on cinchona, though I feel that after Mr. Christie's recent admirable little essay, there is not very much to be said. The advances in practical experience regarding this product has been very great, and in many cases I fear very bitter, during the last year or two. We have learned where cinchona will not

grow, and that is an important point gained. I must, however, differ from Mr. Christie in one point. I do think there has been a very serious deterioration in the vitality of the stock, and I may state that Mr. Gammie, from his long experience of cinchona cultivation at Darjeeling, is of the same opinion. On the Kumbher plantation which included periodical plantings since the original old trees were put out, there is a most marked falling off in the vigour of the trees in successive years. In this case, close planting is certainly not the cause nor is close weeding, the trees growing very wide apart in a wilderness of jungle. Climatic influences are not a satisfactory explanation, the period during which cultivation has been carried on being so extensive. From my experience in Ceylon, I feel convinced that the trees we are now cultivating from seed grown in the island have not the same vigour as the original parents first planted, and that the second generation is even more enfeebled. It also seems to me that, as a rule, the parent trees do not now produce progeny with the same vigour as in years past. The remedy for this would appear to be fresh blood. Regarding the hybrids, a class of plants originating locally, the case seems different, and it would almost appear as if nature were pointing the means by which the gradual extinction of the local cinchona is to be avoided. The subject and many kindred ones connected with the cultivation of cinchona, and the harvesting of its bark, are of great interest, and I should like to enlarge upon them; but time is short, and I must bring this paper to a close.

Speaking generally, it would appear that the most profitable way of cultivating our land in the future is to keep up the very best portions only of our estates in coffee, and to cultivate these highly, spending what we can afford upon them. The bulk of the coffee might then with advantage be lifted and planted with tea, suitable portions of the land being kept in cinchona. To cardamoms, any available forest of the right character might be devoted. On many estates there is unfortunately no forest, and the fact must be faced that for tea cultivation considerable forest reserves are desirable. When no wood is obtainable, the use of coke or fuel brought up by railway will be necessary, and this difficulty and the necessary expense must be faced from the first, and should on no account be ignored or forgotten. It may be of interest here for me to state that tea requires 2½ lbs wood to each lbs. tea, as a rule; therefore, a 500-acre estate, yielding 100,000 lbs. tea, requires 250,000 lbs. or 500 tons wood per annum at least, practically more; where water is not available, a calculation must also be made regarding the fuel required for the engine. For the planting of new ridges and on unfruitful ground where cinchona does not thrive, a product is required. I would suggest also, for the cultivation of fibre plants is undoubtedly an industry to which we shall have to turn our attention in the future. The case in the present, expenditure ceases, save perhaps a few weeding round the plants until they are established. Advantage has been taken by those whose one it appears to be to run down all present and future enterprises, of the somewhat enthusiastic way in which the wholesale planting of new products is advocated by many; and now that their success is established beyond doubt, it is stated that they are being planted wholesale, in suitable and unsuitable localities alike, and further disappointment in the future is predicted. Now far be it from me to advocate the planting of any product in an injudiciously wholesale manner; tea, hardy plant though it is, will not pay on washed exhausted soil, nor on our poor shallow land, and such localities had better be allowed to grow up in jungle after the establishment of some hardy plant, such as the aloes, which is able to hold its own against all other growers. The selection of the portions of estates which are to be maintained as coffee, or planted with tea, cinchona and cardamoms, is a matter requiring judgment and experience, and on the degree of these qualities that is brought to bear on the subject will depend much of the future success of the estate. It is, of course, a matter to which no rules are applicable, and one to call forth all the powers of proprietors or their advisers.

Gentlemen, I have done. In view of the too recent publication of Mr. Armstrong's able and comprehensive essay, my humble effort appears at the greatest disadvantage; but I trust you will make every allowance for the fact that, at a few hours' notice and in the brief space of a portion of a day without any notes and other means of reference, I have had to re-write the greater part of this paper, so as not to come before you with a mere repetition of anything said by that gentleman, and with a view to make my statements supplementary to his, and hence of value and interest to you. If you consider that I have been, in however small a measure, successful in this task, the difficulty of which I only appreciated yesterday when I entered upon it, I shall feel amply rewarded.

T. C. OWEN,
Omonagala, Madulakeles.

—Ceylon Observer.]

CACAO.

THE PREPARATION OF CACAO BEANS.

WE are indebted to Mr. Prestoe, Government Botanist of Trinidad, for a copy of a communication which he has addressed to the *Trinidad Chronicle* on the subject of the curing of cacao beans. Mr. Prestoe is good enough to bear valuable testimony to the merits of the *Tropical Agriculturist*, while he pays the Ceylon planters the high compliment of showing that in the new pursuit of cacao culture and preparation, they have improved upon the methods in use in the West India Colony which is specially associated with cacao.—Trinidad. We reprint the communication, which sets forth with clearness and emphasis

"the benefit of following up the fermentation of cacao beans in their moulage," by clean washing and sun-drying. In cacao, as in tea culture our planters seem likely to take a foremost, if not the first place in the world.

(To the Director of the *Trinidad Chronicle*.)

Dear Sir,—I cannot tell to what extent the *Tropical Agriculturist* is read here in Trinidad. I fancy however only to a very limited extent—probably not more than half a dozen copies being received in the island. This uncertainty on my part must be my excuse in a measure for troubling you for the favour of space for a few words about one of the many subjects that go to make up its contents, and meanwhile allow me, in view of promoting the agricultural interests in Trinidad, to offer my testimony to the really valuable character of this monthly, and which is perfectly unique.

The paper is published by the Messrs. Ferguson of Colombo, Ceylon, who are best known as Editors of the *Ceylon Observer* and *Directory*. It is a book of about 50 leaves, full to overflowing with most interesting and instructive matter, culled from publications in all parts of the world, besides its own original articles and correspondence, and which treat on every possible subject with which a tropical agriculturist, especially a resident proprietor, is likely to be interested in; a striking feature of the correspondence being narratives of the writers' experiences with these subjects or what they know of the experience of others—all with the object of effecting improvement in the agriculture and aiding in the general wealth of their colony.

The special value of this monthly, more particularly as relates to Ceylon, lies in its character as a means—and a powerful one—by the general information it affords for initiating and promoting the cultivation of new or little known products, on the principle of dealing with as great a variety of subjects as the conditions presented in the colony may permit, in preference to concentrating all effort and attention to the development of one or two products, for which the conditions of the country may be best suited.

So far and so successfully has its influence operated in Ceylon (as well as India), that to-day we see—not, as here, the principal exports consist of only one or two subjects, but of a dozen or more.

Some of these besides the leading ones, are on such elastic bases that a leading export showing signs of falling off one year, some product of lesser importance is made to double its output in a single year—as seen at present in respect of Cinchona bark, Tea and Cacao—three striking examples which a perusal of this excellent "*Tropical Agriculturist*" will afford ample information of.

The first two we cannot of course do here—for want of elevation, so that notice of their cultivation would be waste of time—but what of Cacao? With this subject there is an extraordinary increase of output—in the course of three years the export having developed from a few pounds obtained from a few neglected trees in the jungle, and which a happy thought had brought to light by clearing and pruning, to the present considerable export of 151,800 lbs., and which, besides, in the London market—by the beauty of its sample, is the envy of both buyers and sellers, and has accordingly settled down to a leading position in the market at 10s.—abreast of the best from Trinidad.

Of course there is no reason why the very best Trinidad Cacao should not be better than it now is: or that the present Trinidad seconds and thirds, and even fourths (if such can still be cacao) should not be equal or very nearly equal to the present Trinidad best, and thus leave the Ceylon cacao at least a shade behind.

In order to obtain this desirable position it will be necessary—simultaneously with the adoption of a methodical plan for sampling our cacao into about five sets (of varieties)—to follow the system of Ceylon growers: what this is I venture to subjoin an extract from the *Tropical Agriculturist* to show.

From this it will be seen that—as I have previously advocated as indispensable, under a rational method of preparing cacao for the market and for realising the full value of the produce—the *Ceylon planters wash their Cacao*. Here, however, and elsewhere in the West, it is affirmed that to wash cacao is to spoil it both in the operation which breaks the skin, and in its after state: or that it costs too much to be practicable even when the sample is improved.

But these objections arise only from a want of appreciation of the requirements in the operation and—probably—carelessness in conducting it, if even such had been tried. Previous impression of the effects on the beans of the common practice of amassing, sweating, rubbing, drying (which is simply encasing the beans in their mucilaginous covering decomposed and dried with a considerable addition of foreign matter) must for a long time stand as an obstacle in the way of the Creole planter understanding a perfectly clean pale cinnamon brown light bean with easy fracture, as the right sort of sample.

It may be questioned what led the Ceylon planters to wash their cacao—for we may conclude they got no advice from their friends in the West to wash it.

For the answer we may reflect that the Ceylon cacao has been dealt with under the immediate supervision and manipulation, guided by the high intelligence of—for the most part—English and Scotch gentlemen resident proprietors or managers. They were suddenly aroused to the necessity of appropriating to the utmost anything in the way of cacao, and a few old trees neglected for years were at all once made recipients of their most tender regard and attention. The trees were bearing profusely, so that cacao had to be "cured" at once. Old papers and notes on the subject were hunted up, and cacao was found to be cured by being either "sun-dried" or "sweated" and dried, so the sun-drying process being the simplest was started; but then, there was so much mucilage, and after the first day, had become so uninviting in appearance that with their feeling of respect for everything clean, they concluded that their cacao was not going to be the right sort of thing for the English market—(though this was the first new cacao they had ever seen)—even if it could be dried,

so they decided to wash it—for as one told me they could do nothing else with it—but the addition of water so greatly increased the mucilage as to leave it impracticable and besides the skin of the beans broke in the washing and thus the whole thing was thrown away—as actually happened in more than one instance. Further on it was desired to try what "sweating" would do, accordingly beans were put to sweat under the discomfort of wide diversity of opinion as to the period necessary for the "sweating." But being put to sweat, in the course of a few days the mass presented a disgusting appearance of rottenness that washing was again tried as one way of getting out of the fright: this time with very different results. The sweating had decomposed the mucilaginous covering of the beans, and light washing left them clean and as pleasing in appearance as new copper coins. Put at once in the sun, they dried in a surprisingly short time, and soon the result of the prized Ceylon Cacao of sweet mild flavour, cinnamon colour and free 'break,' was attained.

Before all this however a civilised practice in respect of fruit gathering was followed, viz.:

Only the ripe pods were gathered, and thus the beans were uniformly affected in the sweating and drying and came out a uniform sample.

The process herein followed successfully was, therefore, briefly this:

Only ripe pods dealt with; the beans amassed to sweat (being turned once or twice) then carefully washed and put in the sun to dry.

It may here be remarked that the beans being sufficiently sweated to admit of being washed readily, and yet not sufficiently sweated to have fully expanded their cotyledons—i.e., the parts which become nibs—or to have reduced their acidity—can be returned for further sweating after the washing.

The drying being effected immediately after the washing or second sweating, mildewing and discoloration therefrom would never occur, and of course the labour of "rubbing" would be avoided. Necessity for prompt drying renders washing indispensable, for washed beans dry in one-third the time of beans covered with the decomposed mucilage; and as during the wet months artificial means for drying cacao, as employed with tea, is a great desideratum of the time—a point which it is in my chief object in addressing you now to draw attention to—it should not be overlooked that drying by artificial means will not be practicable for unwashed beans—except for re-drying damp cacao, cured in the old manner.

It would be well for the cacao interest generally if, in view of the November and December rains, a practical consideration were to be given to this point at once.

It should never be lost sight of that cacao beans in bulk—not larger than the usual quantity of a "crook" basket or sack and if kept from the air by such a covering as an ordinary sack—will keep fresh and sound for 3 to 5 days, except as to the mucilage which will waste somewhat, as is desirable. Beans might therefore be brought in from all but the most remote parts to be carefully washed and dried at central towns or villages, with great pecuniary advantage both to grower and dealer. I am, &c.,

H. PRESTON,
Government Botanist.

"CURING THE BEANS" (Cacao).

A cooly picks two bushels of cacao beans per diem, and as five bushels wet = 1 cwt., the cost is only about 87c. a cwt for picking, as compared with Rs. 2 to Rs. 3 for Liberian coffee. The pods are first cut from the tree, a small piece of stem being left on the tree, and the cooly takes one in each hand and with a knook breaks them both in halves, and then with one draw of his fingers dexterously strips all the beans off the centre pulp. The pods are then thrown round the trees and as a manure, while the beans are removed to the fermenting cisterns. It takes from 5 to 9 days to properly ferment the cacao, and it is then ready for washing. It is trampled first, as in coffee, with the feet, and then is removed in baskets and carefully handwashed, as washing with the "matapalagai" damages the beans. I have no doubt that ere long some means less expensive will be found for washing, and the clerihew will be much improved on too.

After washing, the cacao is laid on mats to dry as coffee is, if the weather is suitable; and at times it is advisable to give it a rub over with small pieces of sack or cloth, which improves the appearance of the beans, and facilitates drying in this showery weather.

The difference in well cured and badly cured cacao amounts to at least Rs. 20 per cent, and the prices obtained for it as in tea, will depend in a much greater measure on the careful attention of the superintendent to the curing, than in the case of Coffee Arabica, and the good man will have a better chance of coming to the fore, than in days of old with coffee.

CACAO CULTIVATION IN CEYLON.

ESTIMATES AND REMARKS.
(By a Practical Planter.)

Estimate for opening and bringing a Cacao Estate of 200 acres into bearing, including cost of land.

Probable cost of 200 acres of land at Rs25 ... Rs5,000

1st Year, from January to 30th June of following year.

| | |
|--|---------|
| Felling and clearing 200 acres at Rs15 | Rs3,000 |
| Nurseries: clearing sites ... | ... |
| 80,000 baskets at Rs5.50 | 4400 |
| 5,000 cacao pods, at Rs55 | 275 |
| Filling baskets and sowing seed | 250 |
| Erecting pandals for shade | 120 |
| Watering and attending | 125 |

| | |
|---|--------------|
| Lining at R1 per acre ... | 200 |
| Holling: 300 holes per acre 12 by 12 feet apart, 2 feet deep by 18 inches wide (20 per man) ... | 1,200 |
| Billing in 75 holes per man ... | 300 |
| Planting, supplying, and shading at R3.25 ... | 650 |
| | 2,350 |
| Weeding for 18 months at R1 ... | 3,200 |
| Roads: 10 miles with inside drain at R1.50 ... | 1,500 |
| Drains: every half-chain apart, R10 per acre ... | 2,000 |
| Tools ... | 500 |
| Buildings: temporary lines ... | 200 |
| Permanent lines ... | 300 |
| Bungalow, out-houses and furniture ... | 500 |
| | 1,000 |
| Contingencies: medicines and hospital charges ... | 400 |
| Survey ... | 200 |
| Stationery, postage, etc. ... | 50 |
| Chetty's commission on cash ... | 750 |
| | 3,000 |
| Superintendence and allowances ... | 250 |
| Conductor for 6 months ... | 250 |
| | 3,250 |

R18,800

2ND YEAR, from 1st July to 30th June.

| | |
|---------------------------------------|----------------|
| Nurseries and supplying ... | R350 |
| Weeding at R1 ... | 2,400 |
| Roads: upkeep and culverts ... | 400 |
| Drains, upkeep ... | 200 |
| Pruning and suckering ... | 100 |
| Staking at R4 ... | 800 |
| Buildings: bungalow and furniture ... | 3,000 |
| Contingencies ... | 500 |
| Superintendence and allowances ... | 3,000 |
| | R10,750 |

2ND YEAR, from 1st July to 30th June.

| | |
|---|----------------|
| Nurseries and supplying ... | R150 |
| Weeding at R1 ... | 2,400 |
| Roads: upkeep and widening out 3 miles into cart road width 10 feet ... | 800 |
| Drains upkeep ... | 200 |
| Pruning and suckering ... | 300 |
| Staking, retting, &c. ... | 100 |
| Building: temporary curing-house with stores and fan ... | 500 |
| Permanent set of lines ... | 700 |
| | 1,200 |
| Gathering, curing and despatch of 200 cwt. at R6 ... | 1,200 |
| Contingencies, including watchers ... | 900 |
| Superintendence and allowances ... | 3,000 |
| | R10,250 |

4TH YEAR, from 1st July to 30th June.

| | |
|--|--------------|
| Weeding at R1 ... | R2,400 |
| Pruning and suckering ... | 400 |
| Roads upkeep ... | 400 |
| Drains upkeep ... | 200 |
| Buildings, permanent, clerihew, engine, &c. ... | 5,000 |
| Gathering, curing and despatch of 600 cwt. cocoa at R4 ... | 2,400 |
| Contingencies ... | 900 |
| Superintendence and allowances ... | 3,500 |
| Conductor ... | 500 |
| | 4,000 |

R15,700

5TH YEAR, from 1st July to 30th June.

| | |
|---|--------------|
| Weeding at R1 ... | R2,400 |
| Pruning and suckering ... | 400 |
| Roads upkeep ... | 400 |

R28,500

| | |
|---|----------|
| Year's profit ... | R28,500 |
| Value of estate at five years old with only 5 cwt per acre—this is at the rate of 5 years' purchase ... | R140,000 |

As a few remarks on each heading of expenditure in the above estimate will make it more intelligible, I shall endeavour to give this with the aid of information received from friends of larger experience than myself, on many points connected with the cultivation of cocoa. This product being still in its infancy in Ceylon, no authoritative statement can be made as to the best way of cultivating it; but such knowledge as we have has been gained by experience, and can, therefore, be relied on.

The cocoa plant has been in the island for many years (perhaps over 30 years), but till within the last six it was not systematically cultivated. When our attention was drawn to this as a profitable cultivation, we were most fortunate in having at our doors a variety—perhaps the very best we could possibly have had—that has proved, by the vigor of its growth, its fruitfulness, and the range of elevation—from sea level to over 2,000 feet—at which it will grow and yield probably, that it is well adapted to our climate; and the prices realized in the European markets leave nothing to be desired. There are over a dozen other varieties of cocoa in the country, but, till we hear more about them, I would advise our sticking to what we know to be a prime favourite with buyers.

New estates opened were, until recently, planted under the shade of the forest, all the smaller timber being cut out and the larger trees left. This was found in about the second year of growth to be hurtful to the plants, tending to draw them up lanky and weakly. The jungle had, therefore, to be cut down carefully at considerable expense, and where shade has been left, it has been and is still being gradually thinned out. I believe the general opinion now is that direct shade is not good for cocoa, though it remains to be proved whether light and chequered shade is not beneficial.

Land.—The very best land that can be got should be secured for cocoa; the plant is a deep feeder, and to thrive well must have a good subsoil. Dunbar, parts of Matale, and Karunegala have the best soils in Ceylon for its growth—dark friable chocolate of great depth; the vigor of the trees in such soils shows how they revel in it. But, alas! where are we to get soil of this description in any of the forests that are still remaining? Many of the chena lands in the low-country have very fine soil yet (the surface only has been skimmed), but the native titles are very defective; and if one does venture, and purchases small lot after small lot till he gets a fair-sized block, the difficulties and delays in the way of getting a "title of quiet possession" from the Government are most vexatious and almost insurmountable. We must therefore be contented with what we can get, and that is generally inferior soil. Light soil with a good deep subsoil is to be preferred to one with a rich surface soil, but hard impetrable subsoil. Very steep land is to be avoided, but moderately steep suits very well; rich flats are the best. I have only estimated R25 per acre for purchase of land, but, in a few years, when capital returns to the country, and there is a demand for land for cocoa, I fancy it will not be got for double that figure. I have made an error in opening the whole of the 200 acres in the block; to admit of opening 200 acres, the block should have other 50 as a reserve. Even supposing that every acre was available that is suited for planting, it would be still necessary to leave belts as protection against wind, as, however well cocoa will do without shade, it will not tolerate wind. On no account should trees be felled in a locality known to be windy; and after the estate is opened, belts of suitable trees for shelter should be thickly planted in all exposed situations.

Nurseries.—For making these, flat land near water should be chosen, and they should be in 3 or 4 different spots if possible, as this makes the carriage easier when planting out. Pandals of light jungle sticks and covered with small leafy branches must be put up, high enough to admit of a man walking underneath without stooping. The surface soil should then be scraped into heaps, and the baskets filled with this, well pressed down with the knuckles, but not patted as the coole is so fond of doing; the baskets being filled place them 6 deep in a row, and to any distance the space will allow in length; they must be placed perfectly upright, and to keep them in that position a "varachohi" tied to a few pegs driven into the ground on either side of the beds will do. If earth is filled into the spaces between the baskets, at about every 10 or 12 rows across the beds, it will be an advantage. This must be carefully seen to, for, if the coole is left to himself (and kanganyas and conductors are often not one whit better), the baskets are sure to be placed at every conceivable angle but the right one. The baskets being in position, just put one seed in each about one inch below the surface, the broad and downwards—some prefer to germinate the seed before sowing—after sowing water well. Any seed that does not grow in a fortnight should be replaced by a fresh one, and this should be done till there is not a vacancy. Owing to the greater and more rapid evaporation, the outside rows of trees suffer; to prevent this, deep earth against the baskets

The plants should be watered once daily, and in very dry weather twice. I have allowed for enough plant to plant the clearing, and do the first supplying. I have never tried planting at stake, but believe it is sometimes very successful. Should the season, however, be a dry one, the clearing is sure to be very patchy, and I hardly think the risk worth the money saved. Some planters aver that they dare not use baskets, as the white-ants would be sure to attack them and destroy the plants: this is not my experience, except on a very small scale, but, where it is unfortunately so, planting must be done at stake, or plants raised in beds, the seed being sown 4 inches apart each way, and removed by Scowen's transplanter and Davidson's envelopes. This work should be very carefully done, the plants not allowed to remain over 3 months in the nurseries, else the taproots will grow too long, and, in withdrawing the transplanter, the plant, instead of coming out with the soil, will be drawn through it, and all its roots disturbed; such a plant will stand a poor chance in any weather. The transplanter should be frequently dipped in a bucket of water, as it makes the work easier, and the envelopes should be wetted and drawn through ashes; if this is not done the earth adheres to the envelope, and the labor of transplanting in many instances is lost. The shade over plants, whether in baskets or in beds, should after two months be gradually removed to harden the plants. At three months from sowing the seed, the plants are ready for planting out in the clearing. Baskets for raising plants can be got at Kalutara, delivered at the railway station, for from R4 to R4.50 per 1,000, and another rupee should land them on the estate.

Planting.—All distances from 9 by 9 to 13 by 13 feet have been tried, and I believe that most are now agreed that 12 by 12 is the best; this is, of course, for our ordinary red variety: the pale green, white, and purple kinds would want 16 by 16 at least.

Holing.—Some prefer wide and deep holes—wider and deeper than I have estimated for—others prefer narrow and deep. The large holes are more expensive and possibly for the first two years the plants thrive better; with large holes staking is a necessity, whereas with narrow ones it may not be needed. It is well-known that for two years cocoa plants make hardly any lateral roots, sending down only a long tap; during heavy rains, the soil in a wide hole gets very sappy, and the plant having no hold is blown over by the least puff of wind. On the other hand, in the narrow hole, the few lateral roots the plant does make have holding ground at once, and they are thus stayed.

Planting.—This work should be done in the rains, and the earlier in the monsoon the better. One coolie will carry out and plant from 100 to 150 plants either in baskets or transplanter envelopes, according to the distance from the nursery and steepness of land. On hill-sides, the baskets should be buried 2 inches below the lower lip of the hole, so that, in the event of any soil being washed away, the roots of the plants will not be exposed; the earth should be well trampled, and the hole filled flush with the surface, to prevent water lodging and rotting the plant.

Shading should be done the same day as the planting, or the following morning, and tree-branches the leaves of which will stick on for 3 or 4 months should only be used; the best for this purpose are "Mora" and "Kebella." The cost of shading will depend greatly on the facility there is for procuring the proper shade stuffs, and, unless abundant near at hand, enough trees should be left when felling to give branches for shading, and cut down afterwards. In some parts of the low country, the leaves of the "Madu" palm are used; they are like fronds of the tree-fern, and answer admirably. I do not think it is necessary to cover the plant up entirely as is usually done; in my opinion, it is injurious, shuts out sun and light, and keeps hot air confined; and if the shade is attacked by white-ants the plant is bound to go, it cannot escape. The plan I prefer is as follows:—Chop your shade stuff into about 20-inch lengths, stick it upright at about 9 inches from the plant, so that no leaves of the plant touch it; run them along north and south for about 15 inches thus:—

E
N—————S
O
N—————S
W

This will protect the plant from both morning and evening sun, which is really all that is needed, and will also prevent the too rapid drying up of the soil; should white-ants attack it, the plant escapes.

Supplying.—The first supplying should be done in the early north-east rains, and twice more in the following year, by which time nothing further should be needed.

Weeding.—This is a very important work, and it is very desirable that the clearing should be kept clean from the commencement. If the growth of weeds is great, weed once in three weeks till they are got under. It is quite possible that after a year or more the work can be done for 75 cents per acre, but do not resort to this till you are quite certain the rupee is excessive. I need hardly say, permit no scraper or machety weeding!

Roading and Draining.—These works should, if possible, be done before a lining peg is put in or a hole cut—work is facilitated and after-damage prevented, as well as a good deal of vexation and bad temper. The gradients of both roads and drains in the low country should never be steeper than 1 in 15, and for roads intended to be afterwards converted into cart-roads 1 in 25, and less if practicable. Roads should be cut 4 feet in the solid, with a foot deep and wide drain at the back of it: drains should be 18 x 18 inches. The cost of these works will depend much on the nature and lie of the land: if at all steep, what has been estimated will be spent; if flat, a large saving may be expected.

Tools.—As a large force of labour will have to be employed to get through the work in proper time, the estimate for these will not be too much. See that you buy nothing but good articles!

Buildings.—20 rooms, roof and walls of cadjan or talipot, can be erected at a cost of R10 a room, site included—which will be water-tight and comfortable and last for all the time they are wanted; they can be run up in a few days—a great consideration, and there is no risk of the coolies catching illness from wet mud-walls and damp floors. A line of this sort should accommodate

100 laborers. A good deep drain should be cut all round the line to keep the floors dry. A permanent set of rooms can be built at leisure, to serve for those coolies who will remain after the planting is finished. It may seem that the accommodation provided is insufficient for the large force that would have to be employed; but if it be borne in mind, that, in the low country, much of the work would be done by Sinhalese, on contract or day-work, and who would live in the neighbouring villages, it will, I think, be found ample.

Pruning and Suckering.—In the first year, all doubles must be cut away, leaving only one stem. At two years the plant divides usually into three branches or forks, and then begins to make a head. All cross-wood within the centre, and all shoots on the main branches, within one foot of the stem, should be cut out clean; this tends to strengthen the main branches, and prevents crowding when the trees grow older. Twice a year, a month before blossoming seasons, say in May and December, all cross and useless wood should be cut out, so as to let in side light: the crown above should not be touched, as I am inclined to think strong sun, direct upon the young blossom, is injurious. Some planters prune away all drooping branches; this no doubt improves the appearance of the trees, and, when grown under sufficient shade, I quite approve of the practice. In the open, however, they should not be touched as they serve to protect the trunk from the sun, and thus encourage the setting of blossom along it. All suckers should be cut away once a month, and on no account should they be pulled off.

Gathering and Ouring.—The pods when ripe assume a slightly yellowish hue. They should be cut off with a knife close to the pod, leaving the stalk by which it was attached adhering to the tree. If cut off close to the branch, the eyes, on which the future blossoms depend, would be destroyed. The pods are heaped on the nearest road, and, as the husk is very brittle, a slight blow with a light wooden mallet splits it, when the seeds are extracted and put into baskets and carried to the store to be oured. This is done by laying the seeds in a heap, on a platform of reapers and coir matting, and covering it with bags or a tarpaulin. The heap is well turned every two days to ensure equal fermentation, and, on the eighth or ninth day, according to fermentation, it is washed in several waters, till quite clean and free from all mud-lage. If the weather is fine, it is then spread on mats to dry; if not, it is at once put into the clorihew; three days' sun, and less I believe in the drying-houses, will dry it thoroughly, and it is then fit to despatch. Should the moisture not be dried off the beans the day they are washed, they will, during the night, contract mould, which depreciates them in value.

Permanent Buildings.—A bungalow should be begun and finished in the second year: the rooms should be wide and lofty and well-ventilated, with a verandah coming low down all round, and in malarious districts it should have one upstairs-room as a sleeping apartment. The store site should be chosen on a flat, open to the sun all day, and near water. It is built on Clerihew's plan, and should have a steam-engine to work the fan; where there is water, a wheel can be employed, but in the low country few estates have sufficient for this. Opinions differ as to when the store should be ready. One gentleman says:—"I should have my store and machinery up by the time the cocoa is 3½ years old." Another says:—"I would begin to erect permanent stores at the end of the 4th year." I am inclined to agree with the latter.

Superintendence.—This in the first season is allowed for 18 months, as by far the heaviest part of his work will be in the first 6 months, from January to June; he must be on the spot, to give out and supervise felling contracts, and, immediately after the burn, which should not be later than end of February, begin nurseries, erect lines, &c. A conductor is allowed for six months; after that, till the estate begins to crop, no conductor is needed.

Yield of Crop: Estate when in full bearing.—I have estimated 1 cwt. per acre for the third year, 3 cwt. for the fourth, and 5 cwt. for the fifth, and they are reasonable. I have figures before me showing that over the amounts quoted have been picked. With trees planted 12 by 12 feet, 10 pods per tree yields 1 cwt., and, as there are two crops in a year, only 25 pods in each season per tree is required to give 5 cwt. per acre. I cannot ascertain when cocoa is supposed to be in full bearing; but opinions seem to point to 10 years, and a yield of 6 cwt.

Manuring.—With our poor soils, cocoa must be manured, if we wish to get good crops and keep our trees in good vigor. The fifth year is not too soon to begin this. A gentleman writes me:—"I have manured some four years old cocoa with great advantage, and, when it can be done cheaply, I do not think that age too young, it put 2 cwt. an acre on my cocoa at an expenditure of Rs. 22 per acre." If results as good as this were always to follow, I should say four years old was not too young to begin.

Fencing.—This is an item I have not allowed for, but it is one that should appear in every low country estimate. A belt of sapan ten feet wide, the seeds planted 18 inches apart, will, in four years, make an impenetrable fence. At three years old the stems should half-cut through at three feet high and bent horizontally; thus laid, they will continue to grow and send up numbers of suckers. A fence made from sticks of the burnt-off clearing can be put up at the rate of about R2.50 per acre, which will keep out cattle, and, with a few repairs, will last 18 months. When the fence is completed, sow thickly along it on the inside seeds of the tree- cotton, and, as they grow, thin them out to 18 inches apart. In 18 months you will have a live fence that, with two rows of "varacholia" tied across at a very small expenditure, will keep out all cattle, especially if you give notice in the villages that the owners of all cattle caught in the estate without a cross pole round their necks will be fined heavily. I am sure from my experience of low country life that there is more ill-feeling bred between estates

managers and villagers through cattle-trespass, than from all other causes combined, and, if this could be avoided, there would be very little stealing from estates. This is my experience.

Enemies of the Cocoa Tree.—Of these, there are only two that we know at present, and neither is very serious. On individual trees scattered over the estate, the pods are seen to be spotted black, and according to the virulence of the attack the pods are either stunted in growth or killed—trees attacked one year may be quite free of it the next. Those most competent to judge say it is due to an insect, I am watching it carefully, but have not yet succeeded in discovering this insect, and I have my doubts about it; yet the way that only a tree here and there is attacked, looks very much as if it were. The other enemy I believe to be a fungus, though this has also to be established; it attacks the young tips of the branches, destroying them, and often the branch itself for a foot or two back. The tree, however, almost immediately throws out fresh shoots, and, in a month's time, it would not be known that anything had been wrong. I have occasionally seen a second attack follow. This disease is more common when the trees are young, and rare I believe as they grow older.

—Ceylon Observer.]

W. J.

COFFEE.

THE DECLINE OF COFFEE.

IN the Wynnad District, we may infer, gold has had a hand in extinguishing coffee, for on those estates which have been sold to gold companies, the coffee has been entirely neglected. Cinchona, where it has been planted, may thrive, though it is liable to the depredations of similar pests as attack coffee, but, on the other hand, it does not require the annual picking, weeding, pruning, &c., that are needed for coffee. The trees will grow if left alone, but we do not hear of fresh plantings of cinchona where mining is being carried on. It is bad enough for coffee to have nearly died out in the Wynnad, but we read also that in Ceylon the same thing is going on. It appears that there the coffee planter is in a very hard way indeed. The leaf-disease first made its appearance in the island in 1870, and for some time confined its visitations to every other year, allowing an interval for the planter to pick up hope again with alternate good and bad seasons. Latterly, however, the blight has appeared every year, and has resisted all scientific attempts to expel it, and the result of four years' successive leaf-disease is that a great many planters have left the island to seek their fortunes elsewhere, not being in a position any longer to fight against a foe which it appears hopeless to overcome. Those who remain in Ceylon are turning their attention to cultivation other than coffee. Tea and cinchona are the prime favourites, though plants from which sugar and jaggery are produced and cinnamon likewise engage attention. These, with pepper, rubber and tobacco, would, there is every reason to believe, thrive in the Wynnad. Coffee, there is reason to believe, thrives in the Wynnad. Coffee has certainly had a long trial in India, some estates being now nearly half-a-century old. Time was, when colossal fortunes were reared from the bean. The diseases and pests which now decimate the trees have changed all this. Meanwhile Brazil continues to supply the market with coffee, which is a very fortunate circumstance for consumers of the beverage. Leaf-disease is still unknown there, and new coffee districts are opened up every year. Sumatra and Java already produce large crops of coffee, and in British Borneo, the Commissioner is endeavouring to make Tavoy a coffee-producing district. It is by such means as these that the supply will be kept up. It may be that, like the potato, coffee requires fresh land after a certain number of years, and perhaps in a cycle of years the time may come round when Ceylon and Wynnad will again be flourishing producers of the berry, which is now such a source of vexation and disappointment to the planters there. —Madras Times.

MINERALOGY.

THE PRODUCTION OF SIENA EARTHS.

CONSUL COLNAGHI, in his report on the mineral products of the province of Siena, says that Siena earths, known also under the names of ochre, bole, umber, &c., are considered by some mineralogists to be ferruginous clays; by others, minerals of iron. They are chiefly found in large quantities in the communes of Castel del Piano and Aroldosso. The yellow earths and bole found on the western slopes of Monte Amiata are true lacustrine deposits found amid the trachytic rocks, of which it is principally composed. They lie under, and are entirely covered by the vegetable soil. Varying in compactness and colour, they are termed yellow earths when of a clear ochreous tint, and *terra bolare*, or bole, when of a dark chestnut colour. Each deposit consists for the greater part of yellow earth which bole is found in strata or small veins. The mineral being very friable, excavation is easy, and is generally conducted in open pits. Different qualities are separated during the process, the bole which has the greater commercial value being the more carefully selected. After the first separation the bole is further classed into first, second, third, and intermediate qualities—*boletta*, *fascia*, *cercione*, &c. Its most important characteristic is termed, in commercial language, *punto di colore*, or tint. The value of the bole rises as its tint deepens. Thus, bole of the third quality is lighter than that of the second, and the second than that of

the first. After the third quality comes the *terra quilla*. The yellow earths, after excavation, are exposed to the open air for about a year, by the pit side, without classification. The bole, on the contrary, is placed in well ventilated storehouses to dry for about six months. This diversity of treatment is owing to the fact that exposure to the elements brightens the colour of yellow earths, and raises their value, while it would damage the bole by turning its darker tint first into an orange yellow, and if continued, into an ordinary yellow earth. It also loses in compactness and crumbles up under exposure. In addition to the *punto di colore*, the size of the piece influences the commercial value of the bole, which increases with their volume. Thus the classification is *Bolo pezzo*, *Bolo grapolino*, and *Bolo polvere*. The yellow earths are classed as *Giallo in pezzi*, *Giallo commune*, and *Giallo impalpabile*, the impalpable being worth more than the common yellow. The production of the Siena earths is estimated at about six hundred tons per annum of which amount about fifty tons are calcined, and the rest sold in their natural condition. The value of the trade is estimated at from \$4,000 to 20,000.

THE GARDEN.

MICHAELMAS DAISIES.

ASTER (not the so-called German aster) is the scientific name of the very numerous genus commonly known as Michaelmas daisy. In form and colour they are very various, but not very distinct. They are perennials of more or less robust habit and great hardness of constitution. Their chief value lies in their late flowering qualities. Some there are which flower early, such as *Aster alpinus* and *A. longiflorus formosus*, the former appearing in May and June, and the latter in July and August; but the great bulk of them are September, October, and, in some cases where the climate is favourable, November flowers. They are among the last of gay hardy plants to yield their flowers in the open air. And although many speak disparagingly of their leggy, ungainly habit, and of the difficulty of keeping them tidy even with much labour and trouble, yet all who know anything of them must admit that they are the most brilliant among the few hardy things we can rely upon to produce a good effect in the shrubby border long after tender things have become seedy and unsightly. A very limited selection is all that is wanted to supply the distinctive features of the genus, and yield the best of its decorative qualities.

There are other species of hardy herbaceous plants which are coming to be called Michaelmas daisies besides asters, and although there are the best of all grounds for disputing the right of any other flower to the name (that of priority), yet there is no need for us to go out of our way to dispute that which the public has set their heart upon, for the public have decided that botanical names are a bore, and that there are sufficient points of resemblance between the members of several autumn flowering plants belonging to the same natural order, but bearing different generic names, to justify them in giving them one common, popular name, which they have decided shall be Michaelmas daisy. The aster, however, is the best of them all, because it offers a much larger number of forms and colours than any other genus.

The following is a select list of Michaelmas daisies, or true asters, which will give satisfaction in most parts of the country:—

Aster alpinus.—A neat dwarf plant, about 9 inches high. The flowers are pale purplish blue, and appear in May, lasting till July or August. There is a white-flowered variety, which makes a charming contrast to the blue; both are well adapted to the rock-work or the front lines of herbaceous borders.

Aster amellus, and its varieties named *Brunabicus* and *Cassidicus* are attractive, the two first being the best. They are all tall forms, with lilac or slaty-blue flowers, produced in great profusion in September and October.

Aster longifolius formosus.—One of the very best of the species, having numerous large flowers of pale rosy lilac, which open in July and August.

Aster dumosus.—A tall, much-branched sort, with rather small but very numerous flowers of a slaty-blue colour; flowers in September and October.

Aster turbinellus.—A very elegant sort, with gracefully-branched stems and tall growth, and an immense profusion of flowers of pale lilac, appearing in September and October.

Aster disco or.—A freely-branched sort of moderate growth, with very numerous flower heads, with white and violet rays.

Among other distinct and useful autumn-flowering species belonging to other genera, and that are now being called Michaelmas daisies, may be mentioned the following, as very effective:—

Gillardia aristata.—This grows a foot or a foot and a-half high. The flower heads are large, and freely produced from July till the end of October. They are very showy, orange colour.

Helenium autumnale.—This is a striking plant which grows about three feet high, producing large spreading flower heads of bright yellow in August, September, and October.

Pyrethrum uliginosum.—One of the most showy and stately of all these so-called Michaelmas daisies. It grows three, four and sometimes even five feet in height, terminating in large trusses of large pure white flower heads, resembling those of the 'ox-eye daisy.' They are produced in September and October, and in some parts of the country last till November.

Stokesia cyanæa.—A very beautiful plant, wherever it may be, quite hardy, but it is not so in very cold parts. It grows about 18 inches high. The flower heads are large, deep sky blue, and appear in September and October. —North British Agriculturist.

SERICULTURE.

MR. JONES, in his report on the administration of the Central Provinces for the year 1882-83, describes tussar silk as "the most characteristic" of the manufactures of the province. The production of this silk is largest in the districts of Seoni, Bilaspore, Sumbulpore, and Chanda. The rearing of the worms being entirely in the hands of a low, sluggish caste, called Dhimars, no effort of the Government to stimulate the industry has proved effective. In the forest lands of the administration, where the industry is specially exempted from taxation, there is a regular system of rearing the worms which is explained in the report. The tree on which the worms are principally fed is the *saj*, *asain*, or *en* (*terminalia tomentosa*); but they feed on other kinds of vegetation as well. No special rearing sheds are constructed, and all that the farmers do is to pollard the trees, and bend their branches so as to make them accessible to the worms from the ground. They are permitted to wander about at will; but constant watching is necessary to protect them from birds and animals. The rearing commences with the setting-in of the rainy season, and is begun with wild cocoons gathered in the jungles, and not with those saved from the last crop; and during the period occupied thus, the Dhimars, in observance of some superstitious custom, refrain from spirit-drinking and the company of the softer sex. The report then goes on to explain the process of rearing:—

The male and female moths which emerge from these cocoons are allowed to pair, and from the eggs which result, a crop of worms is raised during July and August. The cocoons which are thus produced are merely used for rearing a second crop in August and September, the produce of which is the commercial result of the venture. About 80 worms are, under favourable circumstances, reared from the eggs laid by a single female moth, and about 44 per cent of the moths are females. Assuming therefore that a Dhimar commenced operations in June with 25 female moths, and devoted his first crop entirely to reproduction, his second crop would yield over 70,000 cocoons. It may be noted that on the emerging of the moths which result from the first crop of worms, the males fly off at once, and do not as a rule pair with the females of the same crop. The female moths remain clinging to their empty cocoons, and are fertilized by other males from the outside, who are often, it is believed, attracted from very long distances.

The ordinary tussar cocoons sell at from Rs. 3 to 5 per 1000, and are purchased directly by the weavers, who, having killed the chrysalides by steaming them, wind off the silk after the cocoons have been steeped in an alkaline solution, which acts as a solvent on the glutinous matter that binds the cocoon threads together. The value of spun tussar silk in the Central Provinces is from Rs. 6 to 10 per 2lbs., which is a higher price than the article commands in the European markets.

TUSSER SILK IN CHOTA NAGPORE.

MR. HEWITT, the Commissioner, reports:—About Rs. 89,000 worth of tussar cocoons, manufactured into silk, were exported from Hazaribagh to Moorshedabad and other places, while from Manbhoom and Singhbhum 2,500 and 10,600 kahans respectively of the cocoons were exported during the past year against the same quantity exported from Singhbhum and 7,500 kahans exported from Manbhoom in 1881-82. The Deputy Commissioners of Singhbhum and Manbhoom are both of opinion that the yield of cocoons in the past year in both districts was very large, though the Singhbhum ryots, to whom I spoke on the subject, complained of the small crop they had got; while the Deputy Commissioner of Singhbhum says that the low rate at which they were sold in the market prevented a large quantity from being exported.

I have for several years past been engaged in making enquiries about the tussar industry, which might possibly, under efficient and intelligent management, become a source of great wealth to the Division.

Tussar cocoons at present are grown either in the jungle tracts of Singhbhum and the Tributary States, or in Manbhoom and the villages in the east of the Lohardugga and Hazaribagh districts. In the jungle tracts they are grown chiefly in the jungle surrounding villages in which there is little cleared land, and the yield from these villages is yearly decreasing, as the extension of clearances moves the jungles further from the village site. More than once I have asked the people why they had given up growing tussar in these villages. They have said, "Why, sahib, when we grew tussar, the jungle was close to our houses, but now look how far off it is." As native superstition requires the tussar grower and all his family to submit to a number of ascetic observances, without which a good crop cannot be expected, the people naturally give up growing a crop which entails so much trouble and long journey to the jungles, when they can get very nearly if not quite as large profits from crops grown close to their doors without half the labour and annoyance required by the rules of tussar cultivation.

In the more cultivated villages of Singhbhum, Lohardugga, Manbhoom, and East Hazaribagh the tussar worms are fed on pollarded *asun* trees, some of which have been planted for the purpose, but the greater number are remnants of the jungle which once surrounded the village. The usual number of trees tended by each man is from 10 to 20. The average yield, as far as I could ascertain from enquiries made from a number

of tussar cultivators in Singhbhum, is about 30 cocoons per tree, though in a good year a tree ought to yield about 100 cocoons, so that the average number of cocoons yielded by an average of 15 trees is about 450; and if the price paid be 8 annas per 80 cocoons, all that he and his family get for their watch of about a month, continued day and night, is a little more than Rs. 5-8. If this were all that could be looked for, the number of people who would go through the drudgery of watching, and the minute observances as to cleanliness and food necessary, would be very small. It is only the chance of a bumper crop of 100 cocoons or more per tree that induces cultivators to try their luck in the trade. The number who cultivate tussar is yearly decreasing, and will decline very considerably in a series of years if heavy rain and wind should make the yield as bad as it was last year in Eastern Lohardugga.

On the other hand, a largely increasing demand for tussar is springing up in England, and during my stay there last year, I visited Macclesfield, and spent some days with Mr. Brookhurst, who owns the largest silk mill in that city, and discussed the subject with him, and Mr. Wardle who superintended the preparation of the dyed silk sent by the India Office to the Paris Exhibition, is the head of a large dyeing firm at Lech, and has been for years engaged in making experiments in dyeing tussar.

From what I learnt from them, and from some correspondence I have had with Mr. Wardle, it appears that the English silk firms are prepared to take any quantity of tussar waste at at from 1s. to 1s. 6d. a pound, but that higher prices for unreeled silk would not now pay in England, while at anything like present rates for cocoons here this price would be utterly unremunerative. Now they can get large supplies from China at these rates, but they have no information whether these supplies will keep pace with the increasing demands of the trade, or whether the China worm which feeds on the oak-tree is domesticated or feeds in the jungles. In the latter case the supply is not likely to be largely increased, and a rise in prices, if the demand still continues, may, if the work of production could be reduced, make the export of Indian tussar waste pay.

The China tussar silk is naturally white, and does not require bleaching, whereas it is a very difficult matter to bleach the Indian tussar. The latter is, therefore, much more expensive than the Chinese for all white silks, and can only compete with it at present prices in dyed goods and those of its natural colour; but Mr. Wardle writes to me on the 10th March this year—"I should be much delighted if Indian tussar could replace Chinese; I find it is preferred by the spinners." But except when used as waste, he says—"It must be reeled where labour is cheap," as it will not pay for reeling in England.

The price of reeled China tussar given by him in the letter above quoted is from 5s. to 5s. 6d. per pound; but to make a pound of silk according to Major Cousmaker's experiments requires an average of 436 cocoons; and though the cocoons of Chota Nagpore are larger than those of Bombay, where Major Cousmaker's experiments were made, yet, as far as I learn from enquiries among the natives, his estimate must be considered to represent very fairly the outturn from cocoons in this country. At the rate of eight annas for eighty cocoons, the cost of obtaining a pound of silk would be more than Rs. 2-8, or about the price of the best reeled China silk at home without the cost of reeling. Therefore, before even reeled tussar can pay exporters well, the price at home must be increased, or the cost of production must be materially reduced. Feeding tussar worms on *asun* trees will never pay, as the trees cover a large space, and the yield of the number of trees which one or one family can look after is very small; but if ryots could be induced to plant hedges of *Lagerstræmia Indica* (a shrub on which Major Cousmaker successfully reared cocoons in Bombay) in the gardens close to their houses as they now plant opium and vegetables, the yield of cocoons could be very largely increased. On an acre of wide spreading *asun* trees only about 440 trees, yielding an average crop of about 13,000 cocoons, could be grown; whereas Major Cousmaker has reared an average of 20,205 cocoons to the acre on *Lagerstræmia*, and probably more could be reared on hedges close to a ryot's house, and constantly looked after by himself and his family. But of course the ryots will not do this without the hopes of a large profit, and they must, therefore, be able to get from the small patches of *Lagerstræmia* they can plant in their gardens more than they now get from the few *asun* trees they can look after. If a man now gets an average only of about Rs. 5-8 and the industry is declining, it will require at least an average receipt of Rs. 8 to make the cultivation popular; while, if it could be increased to Rs. 10, the number of tussar cultivators would be very largely increased, but only if a family can look after about an acre of hedge planted about two feet apart, and it is only by experiment that an area a family can look after can be ascertained. In order to make a profit on reeled silk at present prices, it would, considering the expenses of setting up and maintaining flatures with reeling machines, added to those of supervision and transport, be necessary to be able to buy the cocoons at not more than 2s. or Rs. 1 for the quantity required to make a pound of silk. This would be about in round numbers 440 cocoons or 110 for 4 annas—a price much less than that now given; but if, on the other hand, the average yield could be raised to 20,000 cocoons an acre by substituting *Lagerstræmia* hedges for *asun* trees, a ryot could on one-fifth of an acre procure cocoons which he would sell for nearly Rs. 10 a flature.

Here, however, another question would arise—would a ryot and his family look after more than one-fifth of an acre?—and they could not, I very much doubt whether the prospect of getting only Rs. 10 would be held by the more enterprising ryots, such as Koorlies and Koormis, who would alone undertake the cultivation of a *Lagerstræmia* plot, to be sufficient to compensate

them for their trouble, especially as the cocoons must be brought to the flatures before this price could be got. I am afraid this would detract greatly from the attractions which the receipt of Rs. 50 for the crop grown on an acre would present if tussar only required the care requisite for ordinary crops. Therefore, even supposing that a pioneer of the trade did appear possessed of the very sure qualities necessary to overcome prejudices of the ryots, the capital necessary to make a profit after many failures, and a patience not easily discouraged, the success of his endeavours would be doubtful; but if he did succeed, I believe that, owing to the increasing demand for tussar, he would make a large fortune provided the facilities for increasing production in China are not greater than those in India; and as one successful experimentalist would find his example followed by many others, the wealth of the country would be enormously increased by a large and prosperous trade, which would, owing to the cheapness and abundance of labour which the country will probably always furnish, and the probable absence of competition from other countries if Chinese tussar is once beaten out of the market, be likely to be permanent.—*Calcutta Gazette.*

TEA.

COLONEL MONEY ON TEA MANUFACTURE, AND MACHINERY.

THE preface to the first edition of Col. Money's Prize Essay on Tea Cultivation was dated November 1870, and stated that the Essay embodied the results of eleven years' previous experience. The fourth edition, published in July this year, contains, therefore, the mature conclusions of a full quarter of a century of experience of the cultivation and manufacture of tea, in such widely separated and differing portions of India as Darjeeling, Chittagong, the Nilgiris, and the Doars. Had Col. Money paid a visit to Ceylon before this latest edition of his work was issued (and it is strange he did not, considering the ties which bind him to this island), he would have received information and seen for himself a state of things which might have led him to reverse some of his opinions, and deal more fully than he has done with one of the youngest but not the least promising of the tea countries of the world. When Col. Money commenced his career as a tea planter, the idea that Ceylon, already the third coffee country in the world, should threaten even the supremacy of Darjeeling, Assam, and Cachar as a producer of tea, would have seemed as preposterous as the assertion, that ere long tea would be rolled, fired, and largely sifted by machinery, and without the use of charcoal as a fuel. To Col. Money Indian tea planters are largely indebted for the simplification of the manufacturing processes, and the discovery that tea copper pans which the Chinese had used for many centuries, and to which they still adhere as tenaciously as they do to ancestral traditions generally, are in reality superfluous. But time and experience were necessary to convince him and other early planters, that hand-rolling could be completely superseded by machinery, and that the detergent fumes as well as the clear, intense heat of charcoal was not necessary to the outturn of the best tea. Writing of the final firing before packing, Col. Money states:—

"Though I know many planters think the fumes of charcoal necessary and beneficial for the last drying, I do not. I have tried both sun and charcoal, and no difference was perceptible. The former costs nothing, is more commodious, and I always apply it when possible. The sun cannot burn the teas; the charcoal, if the heat is too great, may."

"Whether you use sun or charcoal, put the tea hot into the boxes. The only object of the final drying is to drive off the moisture, which the tea will certainly, in a more or less degree, have imbibed since its manufacture. Even the large zinc-lined bins which should be fitted up in all tea stores, and in which the tea is placed after manufacture, will not prevent entirely damp, so in all cases a final drying is necessary."

We believe that few tea manufacturers now resort to sun, excepting perhaps the makers of green tea in the north-west Himalayan districts. We should like to know, however, the extent to which, if at all, sun-heat is utilized by tea manufacturers in Ceylon. Col. Money states:—

"Sunning between the fermenting and firing processes has no effect whatever on the liquor or the out-turn; but it makes the tea rather blacker, as it drives off much of the moisture in the roll, the firing process after it is shorter and does not consume so much charcoal. What little effect therefore it has is good (for if not continued too long, it does not make the tea too black) and it is economical. I therefore decided on retaining it."

"At the end of the season, however, sunning has more than the above effect. It then makes the tea 'chubby' in form, of a reddish colour, and improves the strength of the liquor."

Col. Money, in the new edition of his book, after "Manufacture," mentions "Mechanical Contrivances." He leans to excess rather than deficiency in withering process; and as to rolling, the result of his experience is that "in all but the point of pekoe tips, hand-rolling is better." No doubt the thorough breaking up of the leaf cells brings out the strength of the tea, provided the juices be re-absorbed and the process of "fermentation" well-performed so as to avoid equally "rasping" pungency and "fustiness" liquor. Col. Money, adhering to the Indian

tradition of a good tea for mixing purposes, still retains the following paragraph:—

"The Liquor.—In taste this should be strong, rasping, and pungent, with, in the case of Pekoes, a 'Pekoe flavour.' There are other words used in the trade to particularise certain tastes, but the words themselves would teach nothing. Tea tasting cannot be learnt from books. If the liquor is well flavoured, as a rule, the darker it is in the cup the better. But to judge of teas by the colour of the liquor alone is impossible, for some high class teas have naturally a very pale liquor."

In India largely, in Ceylon wholly, teas are now made to be used on their own merits and not as fortifiers of weak China stuff. We do not suppose that the table described in the following paragraph has yet reached Ceylon:—

"An ingenious planter, a Mr. McMeekin, in Cachar, invented a rolling table with the object of separating the said leaves. It is constructed of battens, and while rolling the leaf on it, many of the small leaves fall through. The said table is now well known in Cachar, and is in use in several gardens. I have tried it, and find that in a great measure answers its object, but the objection to it is that the leaf must be rolled lightly, and lightly-rolled leaf, as observed, does not make strong tea."

"The Pekoe tips may be, in a great measure, preserved by rolling all the leaf lightly on a common table. But then again the tea is weak, and the plan will not give so many Pekoe tips as McMeekin's table."

"In short, in the present state of our knowledge, except by the hand process (a tedious and expensive one for separating the leaf), strong teas and Pekoe tips are incompatible."

"The difficulty is just where it was, and will so remain until dealers give up asking for Pekoe tips (not a likely thing), or till a machine is invented to separate quickly and cheaply the two said small leaves from the others after they have been all picked together. That such a machine is possible I am certain, and the inventor would confer a boon on the tea interest far beyond the inventor of any other machine, for all the other processes can be done by hand without much expense: this cannot."

Col. Money then goes on to notice such machines and contrivances as he knows of for cheapening the manufacture of tea. Klamond's rolling-machine he originally considered the best, although he did not believe in any machine entirely superseding hand-rolling until he had seen Jackson's which finishes the rolling. The different conditions in India and Ceylon are strikingly apparent in the fact that Col. Money, while speaking of manual, animal, wind and steam power applied to machinery, does not mention waters which is available for the vast majority of our Ceylon tea estates. Col. Money mentions, without having seen it, a rolling-machine invented by a Mr. Gibbon, and a good deal used in Cachar. Col. Money wrote:—

"I only know of one other tea rolling-machine, which is Nelson's. It does not profess to do more than prepare the green leaf for rolling, which, as stated above, is, I think, all that any machine will ever do. I have never seen it working, but it appears simple, being nothing more than a mangle. The leaf is placed in bags, and then compressed under rollers attached to a box, weighted with stones. The prospectus states, it will prepare 80 lb. green leaf in fifteen minutes, and that one man can then finish as much of such prepared leaf in three minutes as would occupy him twelve minutes if the same had not been prepared. I see nothing unlikely in this. The machine, though inferior to Klamond's in its arrangement, ought to be cheap enough to bring it within the reach of all."

"Unfortunately it is not. It is advertised at Rs300, with a yearly royalty of Rs30 the first year, and 20 after. The royalty should be dropped, and the machine sold for Rs150, which would give the inventor a good profit."

We quote again:—

"I have already spoken of one of McMeekin's inventions. His chest-of-drawers for firing tea is, I think, superior to his batten table. It is now so well known, and in such general use, that I shall describe it very shortly. It is nothing more than a low chest-of-drawers, or trays fitted in a frame one above the other, the bottom of each tray being fine iron wire, so that the heat of the charcoal, in the masonry receptacle over which it is placed, ascends through all the drawers and thus dries or fires a large quantity of 'roll' at the same time. By the old plan, a single wicker sieve was inserted inside a bamboo frame called a 'dhole' which was placed over a charcoal fire made in a hole in the ground. On the sieve the roll was placed, and all the heat, after passing through this one sieve, was wasted. Mr. McMeekin's idea was to economise this heat by passing it through several drawers."

"Most planters use these drawers, and there is no doubt in the space saved, and the economy of heat: it is a great step in advance over the old barbarous method, where not only was the heat wasted after passing through one sieve, but a great deal was lost through the basket-work of the 'dhole' itself."

"Still I do not advocate four, still less five drawers one above the other. I think the stream ascending from the lower drawers must, more or less, injure the roll in the upper ones. I confine myself to two, and even then in the top tray leave a small circular space vacant by which the steam from the lower drawer can escape. I utilize the heat that escapes, partially, by placing 'dhallas' in tiers above, with roll in them. These are supported by iron rods let into the wall, and are useful not only for partly drying the roll, but also for withering leaf when there is no sun."

It would thus appear that Mr. McMeekin had anticipated the main principles of the above, and dried now in use. Col.

Money finally noticed an advertisement respecting Jackson's sifting machine, and said its larger size than those previously in use might be in its favour. A machine for sifting and fanning tea at the same time, Col. Money had used, but it did not sort the tea with any nicety, and, although it fanned the tea well, that process might be done by much cheaper appliances. A Jackson's sifter is doing very good work on Abbotford. Space and light, Col. Money truly says, are the great wants for withering leaf in wet weather. Col. Money believed in tea-houses made of iron and glass, and, when the third edition of his book was passing through the press he was sending out glass for a tea-house. He has not, in the fourth edition, related the result, but we can have no doubt it was good. Colonel Money correctly states:—

"One and the principal reason why Indian Tea is stronger than Chinese is that in India the sap or juice is generally retained, while in China it is, strange to say, purposely wasted!"

But Mr. Sillar in England, Mr. Everard in Melbourne, and others whose interests were specially wrapped up in China tea, indulged in the most vehement and senseless denunciations of Indian tea, as awfully unwholesome, just because the juice containing the strength of the tea was not thrown away! After describing the various operations in tea manufacture, Colonel Money wrote:—

"All the above operations should be carefully conducted, but I believe the secret of good Tea consists simply in—*first*, stopping the fermentation at the right moment; and, *second*, in commencing to drive off the moisture immediately after."

"In this article we have dealt only with Col. Money's incidental allusions to tea machinery in his chapter on the "Cultivation and Manufacture of Tea," but in the fourth edition there is a chapter of no fewer than 47 pages devoted to "Tea Machinery," to which we shall advert in a further article. Meantime, we may say that Col. Money pronounces as strongly in favour of Kinmond's drier, as he previously did for Jackson's roller. Kinmond's drier we have not seen, but our experience of Jackson's is very favourable, although we are not yet able to say what the consumption of fuel in the proportion to work done is, as compared with Davidson's sirocco and Kinmond's drier.—*Ceylon Observer*.

TOBACCO.

NOTES ON TOBACCO CULTURE IN THE ANAND, PITLAD AND BORSAD TALUKAS OF THE KHAIRA COLLECTORATE, GUZERAT.

TOBACCO is planted in the "Gorakuveter" lands, which must be well manured to receive it. The land must be ploughed 8, 10, or 12 times and one bigha* requires 20, 25, or 30 cart-loads of manure. The more manure is applied, and the more the land is stirred by the plough, the more plentiful will be the crop, and better the tobacco. In one bigha about 8,000 plants are set, when the tobacco is out, a few of the stalks are left standing, and these send out shoots, which flower and produce the seed. But it is not necessary to water these stalks or to take any trouble about them, and usually only about 20 are left for seed in each bigha. This seed is sown after the first fall of rain in July, on a small piece of ground, well ploughed and manured to receive it, and made up into little beds like garden ground; and if rain does not fall in due time, it must be watered. The young plants are ready to be transplanted into the fields in a month, or a month and half. If they are good and plentiful, one bigha of them will serve to plant 40 bighas, or if inferior 20 bighas; when these plants are sold by one cultivator to another, they bring Rs. 1, 2 and sometimes 3 according to their demand for as many as will suffice for one bigha of land. When the land is quite pulverized, and ready to receive the plants, a large rake (jeall) having 3 or 4 teeth at a distance of 1 inch and 3 tussu (nearly two feet) from each other, is dragged over the field lengthways and crossways, so as to divide it into squares and wherever these lines intersect each other, there the plants are set in. This instrument also ensures to eradicate weeds out of the soil. The planting takes place during the intervals of fair weather within the last fifteen days of August, and the first fifteen days of September, and it requires the land to be moist. If no rain falls for a month or so furrows must be made with the plough, and water let into them. The young plants, when set, must be watered two or three times, and if the sun be powerful, must be shaded until they take root. Should rain fall every 15 or 20 days afterwards water is not required, but if a whole month intervenes without a shower, the tobacco must be irrigated. After the monsoon, it requires watering every 10 or 12 days, and if the water be a little salt, it is preferable to the perfectly sweet water. There are four kinds of tobacco, "Talapdi," "Khandeshi," "Ilatoli," and "Gandla," but only two of these are produced here, namely, "Talapdi" and "Khandeshi," of which the "Khandeshi" has a large thick leaf, and that of the "Talapdi" thin and small. The best and worst sorts of tobacco are not the produce

* One bigha is equal to 23,600 square feet or a square of 160' by 160'.

"ROUGH ON RATS."

Cleaves out rats, mice, roaches, flies, ants, bed-bugs, beetles, insects, skunks, chipmunks, gophers. Druggists, B. S. Madon & Co., Bombay, Gen. Agents.

of particular fields, but depend on the labour, care, and skill of the cultivator, and in some degree, on the quality of the water. The "Khandeshi" tobacco also weighs more than the "Talapdi." The tobacco takes 5 and 5½ months to ripen. It is particularly liable to two misfortunes, one of these is the "hail" or frost in the "ahilali" or cold season, and the other is the rain which sometimes falls about the "holi" when it is out and lying out in the fields to dry. The tobacco is out during the last 15 days of February and during the first 15 days of March. After the "Divali" and end of October, it is necessary to go through the fields from time to time to cut out the sprouts which the plant throws out for flowers, as unless these are removed, the leaves lose the sap necessary to give them their proper flavour. When the tobacco is ripe, it is classed into "kalla" and "jardo." That which is thought good enough for "kalla" is cut down stalks and all, and placed in the field in rows to dry. It remains thus 10 or 12 days, and is then tied up in the early morning, while moist with dew, and carried home and made up there into bundles, with as much expedition as possible; it is the labour of 5 or 6 days to tie up the produce of one bigha, and that of 10 days more to have the bundles, properly turned, dried, and made fit for sale. If the sale does not take place by this time, the bundles are turned every 7 or 8 days till they are disposed. It is an object to sell tobacco, as soon as possible, as it loses weight by keeping, and requires much looking after. The leaves of the plants that are looked upon as "jardo" are removed from the stalks with the bark, and allowed to dry on the ground for 12 or 15 days upside down, and are, then, brought home little by little. The large leaves are then separated from the smaller ones, and the whole is made up into bundles, having layers of large and small leaves alternately. The "kalla" tobacco is used for the "hooka" and for snuff. The "jardo" is used for chewing and for "birla." The tobacco grown here is considered to be the finest, and a sample cured under European agency and forwarded to England fetched a higher price than the American tobacco, but the process of curing is not known, and hence the tobacco as made ready for sale by the cultivators and forwarded, to England did not even pay its own freight. I shall therefore feel obliged by you or any of your readers giving the entire method of curing tobacco as practised in America or at Manila, so as to enable the growers here to compete in the market of London.

V. S. VYAVAHARKAR.

INDIAN CHEROOTS.

INDIA supplies herself with cheroots as well as with tea, but no one will venture to say that her cheroots are at all equal to her tea, though the latter is just as much a manufactured article as the former, and much more difficult to produce in approved merchantable form. The tea industry is much more recent in this country than the cheroot industry, and we would naturally expect to be able to get better cheroots than tea. But the fact is otherwise. And strangely enough, while the price of teas of every quality is being lowered, the price of cheroots is steadily increasing. Again, while the quality of all teas is improving, the quality of all cheroots is, if not degenerating, certainly not improving. The only conclusion we can come to from these facts is, that the tea industry is in the hands of a more intelligent class than the cheroot industry. The cheroot manufacturer seems to understand how to fix the price of his produce on the political economy law of supply and demand, but he fails to appreciate the pecuniary advantages to be derived from an improved quality of production. In this respect he appears to be in the last degree conservative, and to take for the rule of his life the motto, "As it was in the beginning, is now, and ever shall be," and so the quality of the Indian cheroots of 1883 is no better than those of 1833. While Manila competed with India in cheroots of the higher qualities, it was not to be expected that the manufacture of cheroots in this country would improve very much, if at all. Up to the middle of the present century, and for ten or fifteen years thereafter, Manila supplied the Indian market to a considerable extent with cheroots of the higher qualities, and Southern India, of which Trichinopoly was the chief manufacturing town, was content to supply the cheaper and lower quality of article. The price of the best quality of the Manila manufacture was about six times greater than that of the Trichinopoly manufacture. This being the case, it seemed hopeless to expect any part of Southern India, Lower Bengal, or even Trichinopoly itself to make an attempt to compete with Manila. It was said that the best quality of Indian tobacco was far inferior to the medium quality of the best Manila tobacco, and that the best quality of Manila tobacco could not be grown in India at all. Under this view of the industry we can well understand why no efforts were made to improve the best qualities of Indian tobacco. But for the last fifteen or twenty years the Manila cheroot supply has been lost to India, and the quality of the present importations from that country are probably inferior to that of the best Indian cheroots. Practically, the Manila supply has gone, and the Indian cheroot manufacturer has virtually a monopoly of the trade in this country. But as we have said, he has done nothing to improve the manufacture, while he has advanced the price of his produce at least 100 per cent. At first sight, this condition of a rapidly-growing and self-paying industry appears difficult to understand. It seems either that

"BUCHU PAIBA."

Quick, complete cure, all annoying Kidney, Bladder and Urinary Diseases. Druggists, B. S. Madon & Co., Bombay, General Agents.

the whole class of cheroot manufacturers in this country are incapable of discerning their own pecuniary interests, or that it is impossible to improve the quality of the Indian tobacco or quality of the cheroot offered for sale in the Indian markets. When we consider the variety of climate and the various qualities of the soil in this country, there appears to be no good reason why the best qualities of tobacco at least cannot be improved. The qualities of tea, coffee, cotton and wheat have been vastly improved, and tobacco, we think, is capable of some, if not of equal, improvement. Tea growing and manufacture have been studied in China by Indian planters; why should not tobacco planters and cheroot manufacturers go and study the growth of tobacco and the manufacture of cheroots in Manilla? The result would pay, we feel assured. Whatever may be the difficulties in the way of improving the quality of the cheroots supplied by India to her own markets, if there are any real difficulties at all, the fact stands out clearly and lamentably that the Indian cheroot manufacture is not a thriving, but probably a declining, industry—certainly for the higher qualities. It may be said that the manufacturer is quite satisfied so long as he can sell the whole of his produce at a paying rate, and that he has no inducement to improve the manufacture. This view is both commercially unsound and dangerous, and is calculated to raise competition once more from without, or to make the consumer seek tobacco of other qualities, such as are used in the cigarette and the pipe.

Apart from the question of improving the present quality of Indian tobacco, there is sufficient cause of complaint in regard to Indian cheroots as now manufactured. The chief object which the manufacturer seeks to accomplish is apparently to produce quantity, especially in the high-priced cheroots. Thus we find ourselves provided with cheroots of inconvenient length and thickness, dimensions such as smokers do not want. These dimensions are wrought out by the unpardonable sin of packing the interior of the cheroot with tobacco stalks. This packing with stalks should be made a felony at the least, and be punishable under the Penal Code. The smoker does not want the stalks in his cheroot; nay, he totally objects to them, inasmuch as they destroy the flavour of the tobacco and cause many a cheroot, which might otherwise be smoked, to be thrown away unconsumed. If stuffing cheroots with tobacco stalks is little less than a swindle, what shall be said for the other vexatious proceeding of the manufacturer, viz., that of mixing tobaccos of various qualities in one cheroot, and cheroots made of different qualities of tobacco in the same box? This diversity of produce is a sore evil. The purchaser is first deluded in the purchase of his cheroots, and afterwards disappointed when using them. It is the wide experience of the users of Indian cheroots that the qualities even of the best and most highly-priced cheroots are seldom or never similar. Various qualities are to be found even in small boxes of 100 and in bundles of 25, while it is difficult to procure the same quality of tobacco twice over when similar boxes are purchased from the same dealer. How often is the smoker constrained to throw away about half-a-box of cheroots because of the difference in the quality of the tobacco. This waste doubles the price of the cheroot to the consumer. Years go on, and these villainous practices of packing cheroots with tobacco stalks, of mixing tobaccos of different qualities in single cheroots, of packing cheroots manufactured of different qualities of tobacco in the same box, and supplying cheroots of different qualities of tobacco under the same name and brand, continue with unabating regularity, causing the user to believe that the manufacturer does not distress himself in the least about the claims of conscience. The user of the Indian cheroot, who pays Rs. 25 per 1,000 for his purchase, really expends Rs. 50 per 1,000 in the article, because of the variety in the cheroots he buys. It was never so with the higher brands of Manilla cheroots, for all were equal in quality, and none were thrown away unconsumed. For many years some of the long established Bombay European firms imported the higher-priced cheroots from Manilla for their friends. The quality was always good, and the price fair. Subsequently John Treacher engaged in the business, and the supply was always reliable and satisfactory. The price for No. 1 cheroots ranged from Rs. 80 to Rs. 100 per 1,000, which may be considered high in comparison to the price of "trichys" and other similar manufactures, but the Manillas were always of equal quality, and practically the purchaser of 1,000 obtained that number of useable cheroots. The manufacturer supplied what the mark on the box declared the contents to be, and the purchaser was never disappointed. Now that there is no hope of a supply of the quality of cheroots from Manilla, the Indian manufacturer should wake up to his own interest, and improve his produce in the way we have indicated. The public have borne the existing imposition long and patiently enough; it is now time we should have a little reform. Bombay has a large number of cheroot dealers; many of these dealers seem to be able to secure a living by dealing in cheroots alone. Surely, some of these dealers can influence the manufacturer sufficiently to put a stop to the unreasonable practices which check the growth of what ought to be a great Indian manufacture. Let the Indian cheroot manufacture be brought up to the improving level of the tea manufacture, and the public will be satisfied. It is sad to see a thriving industry degenerating in the days of its prosperity, at the risk of commercial suicide.—*Bombay Gazette*.

ZULULAND AND CETEWAYO.

"I know what it is," he answered; "this honey is made from euphorbia flowers, which are very poisonous." This explanation made me feel exceedingly uncomfortable; but I elicited from him that there was not much danger, as the 'maas' taken with it would neutralise the effect of the poison. Directly he mentioned poison I dived into the packs, and pulled out a bottle of ENO'S FRUIT SALT, and emptying a quantity into two pannikins, filled them up with water, and several times repeating the dose, in a few hours we were considerably better."—*"Zululand and Cetewayo," (p 189), by Captain W. R. Ludlow, 1st Batt. R.V. Royal Warwickshire Regiment.*

"What on earth shall I take to Zululand?" asked my friend Jim Law one day at Aldershot, when he had just received orders for South Africa, to start at forty-eight hours' notice. I replied, 'If you take my advice—and it's that of an old traveller—you'll not budge without a few bottles of ENO, even if you leave half your kit behind. I never am without these Salts, and, please the pigs, never intend to be.' On his return I inquired, 'Well, how about ENO'S FRUIT SALT?' 'My dear fellow, it was the best advice you ever gave; they saved me many an illness; and when I left Tsagla, I sold the remaining bottles for ten times the original price!'—*Lieut.-Col.*

JEOPARDY OF LIFE. THE GREAT DANGER OF DELAY.

You can change the trickling stream, but not the raging torrent.

WHAT EVERYBODY SHOULD READ—How important it is to every individual to have at hand some simple, effective, and palatable remedy, such as ENO'S FRUIT SALT, to check disease at the outset! For this is the time. With very little trouble you can change the course of the trickling mountain stream, but not the rolling river. It will defy all your tiny efforts. I feel I cannot sufficiently impress this important information upon all Householders, or Ship Captains, or Europeans generally, who are visiting or residing in any hot or foreign climate. Whenever a change is contemplated, likely to disturb the condition of health, let ENO'S FRUIT SALT be your companion; for, under any circumstances, its use is beneficial and never can do harm. When you feel out of sorts, yet unable to say why, frequently without any warning you are suddenly seized with lassitude, disinclination for bodily or mental exertion, loss of appetite, sickness, pain in the forehead, dull aching of back and limbs, coldness of the surface, and often shivering, &c., &c.; then your whole body is out of order, the spirit of danger has been kindled, but you do not know where it may end. It is a real necessity to have a simple remedy at hand which will answer the very best end, with a positive assurance of doing good in every case and in no case any harm. The pilot can so steer direct as to bring the ship into safety, but he cannot quell the raging storm. The common idea when not feeling well, 'I will wait and see, perhaps I shall be better to-morrow;' whereas, had a supply of ENO'S FRUIT SALT been at hand, and use made of it at the outset, all calamitous results might have been avoided. What dashes to the earth so many hopes, breaks so many sweet alliances, blasts so many auspicious enterprises, as untimely death?

ENO'S FRUIT SALT.—"After suffering for nearly two and a half years from severe headache and disordered stomach, and after trying almost everything and spending much money without finding any benefit, I was recommended by a friend to try ENO'S FRUIT SALT, and before I had finished one bottle I found it doing me a great deal of good, and now I am restored to good health; and others I know that have tried it have not enjoyed so good health for years.—Yours most truly, ROBT. BURN, Esq., Post Office, Barrabarra."

SUCCESS IN LIFE.—A new invention is brought before the public, and commands success. A score of abominable imitations are immediately introduced by the unscrupulous who, in copying the original closely enough to deceive the public, and yet not so exactly as to infringe the legal rights, exercise an ingenuity that, employed in an original channel, could not fail to secure reputation and profit.—*Advertisement.*

CAUTION.—The rights are protected in every civilised country. Examine each Bottle, and see the capsule is marked "ENO'S FRUIT SALT." Beware if you have been imposed on by worthless imitations. Sold by all Chemists, price 2s. 6d. and 4s. 6d.

THE ART OF CONQUEST IS LOST WITHOUT THE ART OF EATING.—DINNER ENGAGEMENTS.—STIMULANTS.—TOO RICH FOOD.—LATE HOURS.—INSUFFICIENT EXERCISE.—EXCITEMENT, &c.—A gentleman writes: "When I feel out of sorts, I take a dose of ENO'S FRUIT SALT one hour before dinner or first thing in the morning. The effect is all I could wish." How to enjoy good food that would otherwise cause biliousness, headache, or disordered stomach—use ENO'S FRUIT SALT.

PREPARATIONS IN SIXTEEN LANGUAGES HOW TO PREVENT DISEASE.

Prepared only by ENO'S FRUIT SALT WORKS, HATCHEM, LONDON, S.E., by J. O. ENO'S Patent.
